In the second part the author describes in great detail illustrated by numerous figures and coloured plates twenty cases of toxoplasmosis observed by him in person varying in age from 10 days to 53 years all of which were characterized by pathological changes in the retina and brain with a localized ocular manifestation. In two cases the diagnosis was established by finding toxoplasms in the cerebro-spinal fluid while in the remaining cases there were ocular abnormalities resembling those in toxoplasmosis. In eleven of these toxoplasma neutralizing antibodies were demonstrated in the serum, while in twelve cases they were present in the mothers of the patient. In seven patients there were ocular signs and cerebral symptoms suggestive of toxoplasmosis. The author regards the retinal lesion as the most significant symptom in toxoplasmosis of the eye. These may be manifested by necrotic retinopathy, retinal granuloma and focal fundus changes. Among other ocular manifestations were noted optic atrophy, iritis, complicated cataract and microphthalmia. In view of the importance of clues presented by the retina an ophthalmoscopic examination is considered to be indispensable for a clinical diagnosis of toxoplasmosis. The author also draws attention to the frequency of toxoplasmic symptoms in the families of patient which seem to point to familial infection.

Both the up-to-date summary of our knowledge of toxoplasmosis and the original description of ocular manifestation in this disease form valuable contributions to the literature on the subject.

SUMMARY OF RECENT ABSTRACTS*

VI PLAGUE

Epidemiology Rodent Plague

Plague occurred in Malta (and in N Africa, Egypt, Palestine, Italy, Sicily, Rhodes and Corsica) in 1945, and CAUCHI (p 784) reports that there were 80 cases with 22 deaths. Infected rats were detected until early 1947, but not since. In this outbreak in Malta, during the year, 22,902 rats were examined, most of which were *R norvegicus*. BARNETT (p 998) found plague in 20 of them, of which 15 were *R norvegicus*. This is evidently the important rat in relation to plague. Zinc phosphide, arsenious oxide, red squill and ANTU were used against the rats.

ERZIN and PAYZIN (p 426) report an outbreak of plague in Turkey. They treated their cases with sulphonamides and serum, with success.

GIRARD (p 595) points out that the term sylvatic plague is a misnomer in that the rodents inhabit not forest land but steppe country. He claims that all plague in N Africa, French W Africa, Madagascar, the Netherlands Indies and in India, whether in towns, villages or hamlets, is murine, and the only reservoir is the domestic rat. Elsewhere, other rodents are involved, and plague rodents may therefore be distinguished as wild or domestic.

HOPKINS (p 995) thinks that plague has been present in Uganda from ancient times, latent but never absent. There is no sylvatic plague, and the rodent reservoir comprises *Rattus rattus* (previously *R (mastomys) coucha ugandae* which has now been supplanted by *R rattus*). *Xenopsylla brasiliensis* is the chief vector though *X cheopis* is present. For epidemics to occur there must, of course, be intimate contact between rats and man (and the rats are climbers, nesting in thatch or iron roofs) the average rainfall has always been about 45 inches in times of epidemics in Uganda. In the Léopoldville area of the Belgian Congo, WANSON *et al* (p 425) found *R rattus* and some of its varieties, but no *R norvegicus*, 22 species of non-domestic rodents have been recognized. Of the fleas, *X brasiliensis* was the most common on rats, but *X cheopis* was also very abundant. These are rarely seen in houses. Only 1 per cent of the field rodents carried fleas, *X nubicus*, *X brasiliensis* and *X cheopis*. The authors give much information on the rodents and their habits, and on the other ectoparasites found on them.

*The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1948 v 45. References to the abstracts are given under the names of the authors quoted, and the pages on which the abstracts are printed.

The history of plague in the Americas is reviewed by FAUST (p. 476) and by HOEKINGA (p. 171) who comments on the chronic or latent infection form in rodents and on the long period of infectivity of fleas (exceptionally up to 396 days). For control in the face of epidemics the use of DDT together with the rat poison sodium fluoracetate ("1080") is desirable. Immunization with a killed vaccine of organisms grown at room temperature is practised.

In the United States the known area of infection of field animals with plague was extended in 1946 by the discovery of the disease in a prairie dog and in a pool of fleas from these animals (*Public Health Reports* p. 171). In the same journal (p. 513) it is recorded that plague was found in a pool of fleas from Dawson County, Texas. The fleas were collected from pack rats (*Neotoma micropus*). In *Public Health Reports* (p. 1082) an account is given of a fatal human case of plague in California, the first natural infection to be reported in U.S.A. since 1913. In 1947 rodent plague was recorded from 14 western States.

BARRETO & DE CASTRO (p. 171) sum up the epidemiology of plague in Brazil. When it was first introduced, in 1899 it was a disease of the chief ports. In the next period it passed to the cities of the interior, and in the third period, which continues to the present time, it is tending to disappear from the cities and to localize itself endemically in rural zones. It is associated with the storage of various crops in the houses of the people and these crops attract rodents. The principal vector is *X. cheopis* except in São Paulo (temperate zone) where *X. brasiliensis* is more important. Plague tends to increase in spring and autumn after the period of heaviest rainfall, with temperatures between 19° and 24°C., and relative humidity between 68 and 83 per cent. For diagnosis, haemoculture and intraperitoneal inoculation of guinea-pigs are advocated, but gland puncture is not approved. For post mortem diagnosis the bone marrow from unoperated digits is used. For treatment sulphadiazine is recommended. Penicillin has been discarded.

Transmission

LIMA and HATHAWAY (p. 173) have compiled a very extensive bibliography of fleas and their animal hosts and a catalogue of the flea of the world and of the animal hosts. This publication will be most useful as a work of reference. CHABALD (p. 944) has compiled a comprehensive list of rodent and flea concerned in sylvatic plague and in plague of domestic rodent and man. He recognizes the fact that all the Siphonaptera can become infected, and has never found any species of flea incapable of transmitting if they were numerous and acting on a preferred host.

BURROUGHS (p. 244) has calculated the vector efficiency of several species of fleas, and compared them with *Xenopsylla cheopis*. Efficiency is expressed numerically, the number being calculated according to a formula which takes into account various relevant factors. *X. cheopis* was the most efficient of the fleas studied followed by *Xenopsylla fasciatus* and others, but *Dermacentor mordax* showed only low efficiency which may have been a peculiarity of the particular strain used. Transmission by blocked flea is most important, but mechanical transmission also important in epizootics.

SHARIF (p. 947) has studied the nutritional requirements of flea larvae. Usually they live on decaying organic matter containing micro-organisms, and their principal requirements are protein and vitamin. The best diet is dried lake and yeast, blood and wheat flour though it quickened larval development, was not a satisfactory diet for the larvae. The vitamins are probably derived from the associated micro-organisms with the food. *X. cheopis* and *X. brasiliensis* grow better than *X. alba* on flour alone and this probably enables them to survive transport in grain even without rat.

In his studies on the bionomics of *X. brasiliensis*, EDNEY (p 332) records his findings on the factors which affect the longevity of adult fleas, for details the original should be consulted

In Saigon HÉRIVAUX and TOUMANOFF (p 596) observed an outbreak in man although the *X. cheopis* index for rats did not rise to the level of 5 per rat, usually regarded as the danger point This was the predominant flea, but there was no correlation between the index and the course of the epidemic TOUMANOFF and HÉRIVAUX (p 995) draw attention to the well-known fact that the microclimate in which fleas exist may be very different from the climate outside They found that the soil and refuse in which *X. cheopis* flourished were different from those where *X. astia* was found, the former soil was sandy clay, retentive of water, the latter was sandy It is known that the temperature requirements of *X. cheopis* are lower than of *X. astia*, and the differences in soil environments may be a reflection of the fact that evaporation of water leads to lowering of temperature

In a discussion of the part played by *Pulex irritans* in the transmission of plague, SWELLENGREBEL (p 74) makes the point that even if it is eventually proved that transmission by this human flea is important in any place, this should not lead one to under-rate the primary importance of measures directed against that part of the murine population which is living in close contact with man

HOPKINS (p 255) has published a key to the known fleas of East Africa

Aetiology

There is still argument about the identity of *P. pestis* and *P. pseudotuberculosis*, and some workers think that the latter is a variant of the former GIRARD (p 173) does not hold this view, but admits that bacilli from sylvatic plague differ from those of murine plague in that they acidify glycerin, and he thinks that under the influence of phage there might be further change in the direction of *P. pseudotuberculosis* He holds that extracts of plague bacilli are toxic for rats and mice, whereas extracts of *P. pseudotuberculosis* are not, and suggests that this test may be used to clarify the position ARAUJO COSTA (p 513) has written a monograph on the diagnosis of plague in rats He deals with the methods of differentiating *P. pestis* from other species of *Pasteurella*, especially *P. pseudotuberculosis*, and he strongly advocates the examination of bone marrow of decomposed animals

SANDOR *et al* (p 994) produce additional evidence to show that the antigens of *P. pestis* are not exotoxins or true toxins, but are bacterial antigens Plague antiserum is of the antibacterial, not of the antitoxic, type

Clinical Findings Treatment

MEYERS (p 174) discusses diagnostic difficulties in plague

WYNNE-GRIFFITH (p 704) reports an outbreak of pneumonic plague in Rangoon He does not think that this form of plague is particularly infectious in certain circumstances, the incubation period is short and there is a non-infectious phase for 24-48 hours after clinical onset Immediate isolation should abort an outbreak

MANI (p 74) sums up much work on chemotherapy with sulphathiazole and sulphadiazine, and discusses a broth vaccine used successfully during the war

In a large series of cases treated with sulphonamides WAGLE and COLAH (p 256) found that the best prognosis was in patients with leucocyte counts within normal limits The degree of septicaemia, calculated on colony counts of blood sown on agar, is the main factor in determining severity, and the fatality rate rises as the colony count rises

SIMON and CHASTRE (p. 377) have treated plague patients with sulphamerazine in various schedules and have found that a course of 3 injections (2.5 gm., 1 gm. and 1 gm.) at interval of 8 hours followed by oral administration of 1 gm. every 8 hours is about as effective as a course of sulphadiazine given every 4 hours. They therefore advocate this course of sulphamerazine because the 8-hour intervals are more satisfactory than the 4-hour intervals. For control of epidemics they rely on DDT. The use of cyanoga and kerosene-soap emulsion formerly advocated, is not now advised since it kills off the rats but has no effect on the fleas and is often followed by a sudden rise in incidence of the disease.

TIEN *et al.* (p. 517) report three recoveries in patients with primary pneumonic plague treated with sulphadiazine and they also report that virulent *P. pestis* were found in throat swabs from 4 of 4 symptomatic contacts so examined. The organisms persisted for 6-13 days and at least one of these persons was regarded as a true health carrier.

HEANG *et al.* (p. 598) report a case of pneumonic plague presumably contracted in a laboratory in which cure was effected by streptomycin and sulphadiazine with transfusions and administration of oxygen. Contact were given sulphadiazine and none developed the disease.

A preliminary report by KARACRAKDI and RAO (p. 333) on the use of streptomycin in a small number of cases of plague is very favorable. HADJIAN and VALERO (p. 784) report dramatic success with streptomycin in three cases of bubonic plague which were not responding to sulphonamides and penicillin. QUAY *et al.* (p. 597) find that streptomycin is the most effective therapeutic agent yet discovered for the treatment of all forms of plague in mice and guinea pigs and they suggest that it should be given early in human plague—2 gm. daily in bubonic, and 4-6 gm. daily in septicemic and pneumonic infections—together with antipest serum if there is profound toxæmia. MEYER *et al.* (p. 597) show that after intranasal instillation of virulent *P. pestis* in suspension in mice and guinea pigs there develops a primary pneumonia, like that seen in man. Immunization with avirulent or chemically killed *P. pestis* confers marked protection, and concentrated antipest serum protect and has some curative action. Sulphonamides are not very effective in pneumonic plague unless used with serum. Streptomycin is the most effective therapeutic agent known. For human pneumonic plague daily doses of 4-6 gm. streptomycin should be given early and continued for 8-10 days.

Immunization Control

MEYER and FOSTER (p. 596) show that agglutinin test, complement fixation test and white blood test have proved inadequate to assess the immunity provoked by inoculation of plague bacilli, and they have applied a mouse protection test with the serum of inoculated person to the subject. When the death rates and the survival times of the mice are taken into account, it appears that inoculation with a purified fraction antigen produces good antibody formation, that formalin killed bacilli and one strain of living avirulent organisms are much less effective, and that the famous Tjander strain is used in this experiment is not immunogenic. Adequate protection requires reinoculation with booster doses.

In control of outbreak in Haifa POLLOCK (p. 597) relied on residual DDT spray for building, DDT dusting powder for personal use and treatment with sulphadiazine and streptomycin. More permanent anti-pest measures are taken when possible but the immediate measures outlined offer the best means of quick control.

Within a week of the application of 5 per cent DDT powder to rat burrows and run in shore warehouses to in S. Carolina, the flea were absent

completely eliminated from rats NICHOLSON and GAINES (p 598) could not detect any significant degree of recovery on the part of the flea population three months later, and there was no better result from the use of 10 per cent DDT powder

Charles Wilcocks

MALARIA

BEDFORD, P D Persistent Malarial Infestation in Fully Mepacrinised Troops
[Correspondence] *Lancet* 1949, Apr 9, 627

This correspondent refers to the possible reservoirs of malaria among parasitized ex-Servicemen returning to temperate zones after service in the Tropics While serving in the R A F he decided, in attempting to compute the magnitude of the potential reservoir, that a minimal estimate could be formed from the number of healthy servicemen without a history of malaria who had been on regular suppressive mepacrine, but who harboured parasites in the peripheral blood Such men, on returning to Britain "would escape the blood examinations normally carried out on those with a history of overt malaria"

In late 1945, he selected 100 airmen all of whom fulfilled the following criteria —

(1) They had spent at least a year in the Far East under primitive conditions in hyperendemic malarious zones

(2) All had been taking 0.1 gm suppressive mepacrine for at least a year and had appeared to have absorbed it

(3) None had had a major illness nor a history nor evidence of malaria, proved or "clinical" in the past year

(4) All were fit at the time of sampling and had been in an area of low endemicity for over three months of the cool season they were "due for home" in a few months

Thick blood films stained by Field's method showed that five of the hundred men had *P. vivax* gametocytes in the blood

The author discusses the future epidemiological significance of this finding, bearing in mind that latent malaria may declare itself after an incubation period of many months and he suggests that, even though indigenous malaria arising from returned servicemen is negligible up to now, "the detection and cure of even 5 per cent of healthy 'carriers' may well be considered as a rational public-health procedure" should the position change at some future date

H J O'D Burke-Gaffney

ZANETTI, V & LAMBRECHT, F L Notes sur la malaria indigène au Nepoko
[Indigenous Malaria in Nepoko] *Ann Soc Belge de Méd Trop* 1948,
Sept 30, v 28, No 3, 355-70

The Nepoko Valley is in the Stanleyville Province, Belgian Congo, 2° 30' N, at an altitude of 800 metres Rainfall is abundant, 2,000 mm a year November to January, inclusive is a relatively dry season, as are two or three weeks in July—August Anopheline density is low, *A. gambiae* occurs The population is agricultural there are no large centres of population

The blood was examined of 1,562 persons, of both sexes and all ages, attending three rural dispensaries for any reason, between April and December Malaria parasites were found in 547, 35 per cent, all *P. falciparum* crescents were found only eight times These 1,562 included a certain number of patients seeking treatment for acute malaria

During the same period, the blood of 160 women admitted to the Maternity Hospital at Pawa wa examined. All harboured malaria parasites, for the most part very few in number.

Other observations confirm the fact that the parasite index in this region is low compared with other part of the Belgian Congo. Clinically malaria is a mild disease among adults but may be very severe among infants. It is a very important cause of infant mortality.

Paludrine has been used both for treatment and prophylaxis. For treatment children from 1 to 3 years were given 0.03 gm. a day older children 0.1 gm. a day and adult 0.3 gm. a day for 10 days. Against schizont the action of the drug was rapid and potent against gametocytes negligible. In 4 cases mature schizont of *P. malariae* appeared in the blood during the first week of treatment and after *P. falciparum* had disappeared. Paludrine was ineffective against the sexual forms of *P. falciparum* and against *P. malariae* than either quinine or atabrin mepracine though very effective against *P. falciparum* schizont. It rapidly reduced splenomegaly.

In examining the blood of 1,873 persons of all ages the authors found microfilariae of *A. ochrochelonema perkinsi* in 927 49.5 per cent. and of *Loa loa* in 230 12.3 per cent. 1 *perkinsi* was found in 3 and *Loa loa* in 2 of 112 infants whose blood was examined during the first five days of life.

Norma Waite

SWELLENGREBEL, N. H. & SWELLENGREBEL, J. M. H. Malariaheersetting in de openvogende bevolijde klassen over autochthone bevolijung in hoog endemische malariegebieden der N.O. kust van Nieuw-Guinea. [Malaria Infection in Successive Age-Groups among the Indigenous People in Hyperendemic Malarious Areas in the North-East Coast of New Guinea.] *Nederl. Tijdschr. v. Geneesk.* 1945, Oct. 30. 82 (n) No. 44 3193-3214 4 graphs. English summary.

The human response to hyperendemic malaria is compared as it occurs in Sumatra, S. Africa, Sumatra and New Guinea. The West Indonesian form is characterized by uniform high spleen rates in all age groups while the high parasite rates in young children diminish with advancing years. The African form is characterized by high spleen rates in young children and lower ones in adult and this is combined with parasite rates which in children are double and in adult treble the W. Indonesian rates. On the other hand, the natives of hyperendemic areas in New Guinea show a parasitic response which closely approaches the African type and a splenic response which is intermediate between it and the W. Indonesian type. There is a gradual but not a fundamental difference between the two types. This difference is best explained not so much by racial peculiarities as by the rising immunity resulting from increasing rate of infection this in turn tend to diminish splenic action.

P. Manton-D. Jr.

YAO, Y. T. Synopsis of the Epidemiology of Important Parasitic Diseases in China. Part I. Malaria, with Keys to the Chinese Anopheline Mosquitoes. *Chin. M. J.* Chengtu Edition 1945 Apr. 63A No. 3 103-20. (Numerous ref.)

The summarized information was put together for the benefit of Chinese and foreign medical members of armed forces in China. Of parasitic diseases malaria kala-azar schistosomiasis and hookworm infection are of the greatest importance to China. Part I of the paper deals only with malaria.

Malaria is widespread in China and *P. falciparum* infection occurs all over the country. *P. falciparum* infections are only found south of 35°N.

where they are most prevalent in hilly regions. Endemic malaria throughout the country is predominantly due to *P vivax*. A summary of the salient results of numerous malaria surveys in different parts of the country is presented in tabular form. Blackwater fever is relatively common in Yunnan and Hainan Island, elsewhere it is very rare.

Thirty-seven species and varieties of *Anopheles* have been identified in China, these are listed with notes on geographical distribution of each. Seven species have been incriminated as vectors: *A minimus*, *A jeyporiensis candidiensis*, *A maculatus*, *A hyrcanus sinensis*, *A pattoni*, *A maculipennis atroparvus*, and *A sacharovi*. In hilly regions of the south, *A minimus* and *A candidiensis* are the most important vectors. In hilly regions of the north, *A pattoni* is probably an important carrier. *A sinensis* is the chief vector throughout the plains of China. *A atroparvus* is of local importance in Heilungkiang in the north-east and *A sacharovi* in Sinkiang in the north-west.

Keys are annexed to facilitate the identification of both adults and larvae of all species hitherto reported from China.

Norman White

FAUST, E. C. & HEMPHILL, Faye M. Malaria Mortality and Morbidity in the United States for the Year 1946. *J. National Malaria Soc.* 1948, Dec., v 7, No 4, 285-92, 3 figs (folding maps).

This is a yearly statistical analysis of the incidence of malaria in the U.S.A., illustrated by detailed tables and maps showing the morbidity and mortality in each State, for information on which it must be consulted in the original.

Between 1931 and 1938 malaria incidence increased considerably, and towards the end of the war returning soldiers provided many exogenous cases as well as a parasite reservoir from which others became infected, and about this time DDT came into use. Diagnosis has also improved. The effect of each of these factors cannot be disentangled from the total picture which shows a decrease in reported deaths from a maximum of 4,678 in 1933 to 341 in 1946, and in reported cases from 136,433 in 1935 to 47,903 in 1946. The authors have some critical comment on the reliability of data. They conclude that malaria is steadily declining, and in formerly hyperendemic areas is changing from an acute to a mildly chronic, essentially quiescent form.

G. Macdonald

WEYER, F. Die "Rassen" von *Anopheles maculipennis* in Deutschland [The "Races" of *Anopheles maculipennis* in Germany] Reprinted from *Ztschr. f. Parasitenk.* 1948, v 14, 33-59, 17 figs [13 refs].

Only *A. maculipennis atroparvus*, *A. m. messeae* and *A. m. typicus* occur in Germany. This paper first recapitulates the well-known problem of the morphological differentiation of these races and, in addition to the textual descriptions of the various stages of the mosquito, gives figures of the male claspette, the larval head, palmate hairs, and thirteen photographs of the diagnostically important egg patterns. It then goes on to outline the geographical distribution and biological characteristics of the three races.

A. m. atroparvus is primarily a coastal species breeding in brackish water, its eastern limit being Frische Haff. It occurs, however, 30-60 kilometres inland along river courses, e.g., the Elbe, and has been found as far inland as near Bochum and Paderborn in Westphalia, Hümmling in Emsland, Bad Oldesloe and Bad Sülze in Mecklenburg, also near Eisleben, Magdeburg and

Görlitz and in East Germany and the Black Forest. In inland regions the water may be fresh or salt. It breeds in animal watering ponds, weedy stagnant ditches, swampy pools, drains and often in small open pools with limited vegetational growth. Precipitin tests have shown *strophurus* to feed on pig, horse, cattle, goat, sheep, rabbits and less frequently on man in nature but it will feed on man readily in captivity. The adults are found in spring and summer in stables, cattle-sheds, pigsties, rabbit hutches, sheep and goat sheds but not in fowl houses or kennels. During hibernation they rest mainly in lofts, barns and empty out-houses but some are to be found in occupied animal sheds. These are *strophurus* females which, since hibernation is only partial, have recently fed on the stalled animals. *A. maculipennis* females resting in occupied animal sheds in winter are always *strophurus*. Hibernation extends from September until the end of March. Winter blood meals require at 20°C. 2-3 days for digestion and 15-20 meals are required under experimental conditions for egg production.

A. m. messiae is the commonest race in Germany and is essentially an inland, fresh-water breeder. It is the only race occurring along the East Prussian coast, but the salinity of the breeding places there is not certainly known. It breeds in low lying marshy areas, in ditches, in standing water along the course of rivers or in the weedy edges of lakes. It occurs for example in the lake district of Mecklenburg and of Upper Bavaria, at Lake Constance and along the valleys of the Oder, Weser, Elbe, Rhine, Danube and Neckar rivers. The adults are found in summer in stables and cattle-sheds, less usually in pigsties and it is frequent in fowl houses and kennels. It hibernates completely and in the same type of resting places as *strophurus* except in stalls actually occupied by animals. *A. m. messiae* does not feed readily on man or rabbits in the laboratory but will do so on fowls. A high percentage contain blood in nature possibly of water fowl.

A. m. typicus is not found in the north sea-coast region of Germany. It is the least common of the three races and, although essentially a mountain race occurring in the Harz Mountain and the Black Forest, known from Mecklenburg, Westphalia and near Muehlburg and Görlitz. It is sometimes found in the same breeding places as *strophurus* and *messiae* in the Black Forest it is known from null ponds constantly refreshed by the cool water of mountain streams. Nothing is known of its host preferences but it is found in cattle-sheds in the Black Forest. Its hibernation habits are thought to be similar to those of *messiae*.

A. m. alpinus is monogamous, *messiae* and *typicus* are polygamous. A section records briefly the varying degrees of fertility between the races none of which when crossed are known to be capable of producing fertile progeny.

This paper contains nothing that is new concerning the biology or morphology of these races. It is a useful summary of the subject in view of the remarkable increase in the incidence of malaria in Germany since the end of the war. The Bulletin 1948: 45-109. The author states that the recent incidence of malaria in Germany is not due to a close relation between *Anopheles alpinus* and the human population as occurs in Holland but that transmission in such places as Berlin, Brandenburg in Württemberg and in the Rhineland is by *messiae*. In the reference quoted, the same author remarks that many new mosquito breeding places have appeared in Germany as a result of war-time destruction e.g. in neglected ruins, bomb craters, in neglected ornamental ponds and parks and as a result of beached dams and river banks or the blockage of water courses. In one year more than 1000 *Anopheles* breeding places were reported in Berlin. Another paper however gives concrete evidence incriminating *messiae* as the vector of the recent outbreak of malaria in Germany.

WHITE, R Senior **Malaria Transmission in the Light of Modern Evolutionary Theory applied to Malaria-carrying Mosquitoes** *Indian J Malariology* 1948, Mar-June, v 2, Nos 1/2, 13-33 [34 refs]

The author points out that even within the limits of Asiatic *Anopheles* there are several species which transmit malaria in a part of the area but not elsewhere. *A. sundaus* may cause an outbreak of malaria in a certain place, but at other times transmit the disease very rarely. Other small but constant differences exist within the limits of a species in the conventional sense. These and many other facts point to the existence of units of less than specific rank differing mainly in physiological characters [though it might be added, one must be cautious in considering the facts, some of which might be due to changes in the environment].

In considering these matters the author has been much stimulated by reading *Evolution—the Modern Synthesis* by Julian HUXLEY (1942). In this paper he makes extracts from that book, calling attention to the large number of similar cases which are recorded from other groups of insects. For instance, within a species there may be separate races which are adapted to different foods, there are what one might call psychological differences which reduce the cross-mating between groups within one species. The question of the distribution and spread of mutations through a population is also considered. Huxley has also called attention to that interesting phenomenon, the development of races of insects resistant to insecticides. The evidence seems to show that in certain scale insects and in codling moths a strain resistant to cyanide fumigation has been produced, which is also abnormally resistant to other toxic substances to which it has not been exposed. This phenomenon of a development of general rather than specific resistance is difficult to understand and, in Senior White's view, fundamental. He feels that before so very long we shall be forced to abandon the use of insecticides, even the most powerful, and that we shall achieve control to a great extent by the use of biological methods. The entomologist who has recently felt that his job may vanish because of the activities of the organic chemist will take courage.

The paper is full of interesting material and ideas. We have found it difficult to summarize. The author's conclusion is that there is a call "for investigators who will apply and extend the methods of pure zoological research to the problem of biological mosquito control."

P A Buxton

DE GAETANI, G F **Patogenesi della malaria. Stato attuale delle ricerche [Present Knowledge of the Pathogenesis of Malaria]** 58 pp, 1 coloured pl [Bibliography] Reprinted from *Atti Accad Sci di Ferrara* 1946

A general review

TAYLOR, H L, MICKELSEN, O & KEYS, A **The Effects of Induced Malaria, Acute Starvation and Semi-Starvation on the Electrophoretic Diagram of the Serum Proteins of Normal Young Men** *J Clin Investigation* 1949, Mar, v 28, No 2, 273-81, 1 fig [31 refs]

V HALLER, E **Die Erkrankungsdauer der Malaria (insbesondere der Malaria tertiana) [The Duration of Malaria, especially *P. vivax* Infections]** *Ztschr f Hyg u Infektionskr* 1948, v 128, Nos 3/4 379-87, 1 fig [25 refs]

These original observations were made from June to September 1945 in a prisoner of war camp at Rimini on the Adriatic and appeared to show that 1½ years from the last infection no further relapses occurred and that all risk

of sequelae had then ceased to exist. The material consisted of 1,202 soldiers originally infected in Sardinia (the majority had suffered from relapses (in the region of 60 per cent.) They had left Sardinia in September 1943. Without going into details the author feels justified in concluding that the duration of infection in tertian malaria seldom oversteps the two-year limit but usually no symptoms are manifested after 1½ years. That this is due to the disappearance of the parasite is suggested by the fact that it occurs before immunity is produced and while the patient is still susceptible to a fresh infection. In direct contrast are the findings in therapeutic malaria produced by blood inoculation. Here relapses seldom, if ever are noted after two months and only when the treatment has not been sufficiently vigorous. In the sterile period the blood is infective for mosquitoes while in the naturally contracted malaria this is not the case. In subtertian malaria relapses do not occur after a latent period of eight weeks and the infection seldom, if ever persists for one year in the human body (see also this Bulletin 1948 v 45 970).

VAN DER ENDE H. Enkele gevallen van beenmergreterming door malaria. [Some Cases of Bone-Marrow Inhibition in Malaria.] Nederl Tijdsch v Geneesk 1949 Jan. 15 v 93 (1) No. 3 163-9. English summary (4 lines).

Ten cases of varying degrees of bone-marrow inhibition in each of which malaria (usually *P. falciparum*) was commonly the only ascertainable factor. The anaemia was severe accompanied by slight leucopenia and thrombocytopenia. megakaryocytes were also present. Malaria therapy was followed by great clinical and haematological improvement in each instance.

ROBERTS J. I. Dysentery associated with Malaria. J Trop Med & Hyg 1949 Apr 52, No. 4 78-R.

Further details are given of cases of dysentery occurring in the course of a malaria epidemic in Nairobi, Kenya, which was originally described by Hirsch in this Bulletin 1941 v 38 230. The dysentery was of a milder type the stools not usually exceeding ten in 4 hours. Pus cells were rare in the stools the blood was often bright red, but occasionally dark as the result of petechial haemorrhages in the intestinal mucosa. Malaria was believed to be the cause of the dysentery because (1) the condition responded very rapidly to quinine treatment, (2) malaria parasites were found in the peripheral blood and in blood contained in the stool, (3) the cases were associated with high fever and headache and (4) dysentery organisms were rarely recovered from the faeces. The leucocyte count was generally within normal limits.

These cases are unlike those of true intestinal malaria a pernicious syndrome of *P. falciparum* malaria, which is much more severe and fatal, and shows developing and mature schizonts in the blood. In this series rings and gametocytes only are reported.

VAN SITJEN P. B. Enkele opmerkingen over de behandeling van malaria. [Observations on the Treatment of Malaria.] Nederl Tijdsch v Geneesk 1948 Dec 11 92 (15) No. 50 4044-42. English summary (5 lines).

In a person who has been repatriated from Indonesia malarial relapses are caused by the benign tertian parasite. In the question of appropriate treatment the whole problem of malaria therapy is discussed and it is concluded that the

best course of treatment to prevent relapses is a combination of quinine and pamaquin in a series of short courses of low dosage. The problem of nutrition is also important. *P Manson-Bahr*

DREISBACH, R H Antagonists for Fatal and Non-Fatal Doses of Quinine Intravenously in Depressed Circulatory States and in Hyperthermia *J Pharm & Exper Therap* 1949, Mar, v 95, No 3, 347-51

"1 Pamaquine, pentaquine, and isopentaquine chronically administered to dogs produce impairment of sympathetic cardiovascular reflexes, but not of parasympathetic or respiratory reflexes

"2 Pentaquine and isopentaquine, but probably not pamaquine, cause similar effects in the monkey

"3 The impairment of reflexes is believed to be due to destruction of medullary cell-groups"

COLETTE, Mlle & POROT, M Les psychoses quinacriniques [Psychoses attributable to Quinacrine] *Algérie Med* 1948, Aug-Sept, No 7, 375-86 [15 refs]

The authors describe nine cases which came under their personal observation within a period of one year in which the patients developed acute mental derangement after the administration of quinacrine [mepacrine] in therapeutic doses. Five of the patients had a history of some form of mental trouble in the past, melancholia, short or prolonged confusional states, anorexia nervosa or the like. In six of the nine cases malaria could be definitely excluded as a possible contributory cause of the mental derangement. The onset of mental symptoms occurred very shortly after quinacrine treatment, within a week at most, except in one case where mental symptoms did not appear till one month after the ingestion of 3.5 gm of the drug.

All the patients had maniacal symptoms, accompanied in some cases by a confusional state, often by an anxiety state, at times intense, and sometimes by very painful hallucinations. The symptoms lasted for one to six months except in two cases in which mental symptoms were of only two and ten days' duration respectively. The ultimate prognosis is good in all cases. There is no specific treatment. Six cases were treated by electro-shock, the best method of calming maniacal agitation. In one case insulin coma was used with success.

The authors consider that quinacrine should be avoided in the treatment of patients with a history of past psychosis, or of patients in a state of mental disequilibrium. A warning is also given against a too hasty diagnosis of malaria, on insufficient grounds.

SCHMITT, C L Present Status of Quinacrine (Atabrine) Dermatitis. Report of Six Cases. *Arch Dermat & Syph* 1949, Jan, v 59, No 1, 16-21

The author distinguishes two distinct types of quinacrine [mepacrine] dermatitis. (1) The lichenoid type which is generally recognized, and (2) an

eczematoid type which he considers to be ten times as common. This second variety is characterised by patches of closely set, dome-seated millary vesicles first appearing on the sides of the fingers and subsequently affecting the wrist and less frequently the feet, legs, ears, scalp, suprapubic region and scrotum. While the original eruption tends to heal a recurrent eczematoid dermatitis may occur months or years afterwards. The recurrent dermatitis is similar in appearance to the original one and may occur at previously affected sites or elsewhere.

MONTHLY BULL. MINISTRY OF HEALTH & PUB. HEALTH LAB. SERVICE
(DIRECTED BY MED. RES. COUNCIL) 1949 May & 8 97-4 Recommendations on the Use of Paludrine (Proguanil) in Prophylaxis and Treatment of Malaria. Also in *Brit. Med. J.* 1949 Apr 2, 985-6 & *Lancet* 1949 Apr 2, 579-9.

"The following recommendations on the use of proguanil ('paludrine') in the prophylaxis and treatment of malaria and suggestions for trial are issued by the Colonial Office and the Medical Research Council on the advice of the Colonial Medical Research Committee. It should be clearly appreciated that the recommendations are tentative on the basis of present knowledge and that they are subject to review in the light of future experience and experiment.

Prophylactic Use

The dose recommended for suppression of malaria of all types in endemic areas is 100 mg. daily. For children the following dosage is advised: from birth to 5 years—25 mg. daily; from 6 to 1 year—50 mg. daily. When a daily dose is not practicable one dose of 300 mg. should be taken on the same day each week; dosage for children should be in the proportion indicated.

"In the case of persons other than the indigenous inhabitants who have been resident in an endemic area for some time or who have been otherwise already exposed to malarial infection, a full therapeutic course (see 1 () below) should be taken before entering on the suppressive regimen.

1. *P. falciparum* (Malignant Tertian) Infections. Mixed Infections. Undiagnosed Type Infections.

"() *Treatment of Non-immunes.*—Proguanil alone cannot be relied upon to effect radical cure in all cases and the clinical response with this drug unaided is also somewhat slow. It has been shown, however, that these disadvantages may be overcome by reinforcement with mepracrine on the first day of treatment. The following combined course is recommended for trial: 300 mg. proguanil twice daily for 10 days reinforced on the first day of treatment with three doses of 300 mg. mepracrine and followed by 100 mg. proguanil daily for six weeks. (Persons continuing to live in an endemic area should continue their suppressive regimen.)

(b) *Treatment of Clinical Attack. Semi-immune Subject such as Law Forces and Rural Populations in Endemic Areas.*—A single dose of 300 mg. proguanil will usually suffice to produce clinical cure. Relapses can be treated similarly as and when they arise. Serious cases should be given emergency treatment (see below).

(c) *Treatment of Malarial Emergencies.*—For treatment of conditions such as cerebral or algal malaria and when for any other reason the patient is unable to take drugs by mouth, immediate intramuscular or intravenous quinine therapy should be employed.

2. *P. vivax* (Benign Tertian) Infections.

"() *If the Object is Radical Cure.* The course advised for adults is 100 mg. proguanil plus 10 mg. pamaquine base or corresponding dose of con-

of the other 8-aminoquinoline derivatives) three times daily for 10 days. The dose for children should be proportionate. Pamaquin should not be given unless the patient can be kept in bed under medical supervision throughout the course, this is particularly important in the case of children. When the patient cannot be kept in bed the alternative course recommended is 100 mg proguanil three times daily for 10 days followed by a single dose of 300 mg proguanil on the same day each week for a year.

"(b) *Treatment of the Clinical Attack in Semi-immunes*—As for M T malaria

"Unless otherwise stated, the dosage mentioned is that for adults. In recommending the use of a single dose of 300 mg proguanil for the treatment of the febrile attack in semi-immunes and a weekly dose of 300 mg for suppressive purposes, the advantages of these procedures are emphasized as (a) bringing an effective antimalarial drug within the economic capacity of village and rural populations of endemic areas of malaria and (b) providing a method of prophylaxis easy of administration."

TERZIAN, L. A. & WEATHERSBY, A. B. *The Action of Antimalarial Drugs in Mosquitoes Infected with Plasmodium falciparum*. *Amer J Trop Med* 1949, Jan, v 29, No 1, 19-22

Since only those drugs which acted as prophylactics in the vertebrate host prevented oocyst development in the mosquito, TERZIAN (this *Bulletin*, 1948, v 45, 767) noted, from experimental evidence, that there was a correlation between drug action in the mosquito (*Aedes aegypti*) infected with *P. gallinaceum* and in chickens infected with sporozoites of this parasite. The investigation has now been extended to *Anopheles quadrimaculatus* infected with *P. falciparum*. The earlier experiments with *P. gallinaceum* indicated that if sporozoites were present in the mosquito, they were always infective to the chicken host, and this has been accepted as a valid criterion of infectivity here, since it was not always practicable to test the point on human patients. The drugs used were added in sugar solution to the mosquito diet after they had fed on neurosyphilitic patients undergoing malarial therapy. Quinine, quinacrine [mepacrine], santonin (SN 6911) and sodium sulphadiazine did not prevent oocyst development or affect the production of sporozoites. Paludrine, however, prevented complete oocyst development, although some partly developed forms were present when dissections were carried out on the fourth day after infection. Sporozoites were never present. Similar results have been recorded by FAIRLEY (this *Bulletin*, 1947, v 44, 282). The correlation noted above for *P. gallinaceum* thus appears to hold in the case of *P. falciparum*. This method of drug evaluation in the mosquito should be of value in screening prophylactic drugs in human malaria.

J. D. Fulton

SEATON, D. R. & LOURIE, E. M. *Acquired Resistance to Proguanil (Paludrine) in Plasmodium vivax*. *Lancet* 1949, Mar 5, 394-5

Experimental evidence of induced resistance to various drugs in malarial parasites of monkeys and birds has been provided in the last few years (this *Bulletin*, 1942, v 39, 438; 1943, v 40, 754; 1947, v 44, 969, 970; 1948, v 45, 48, 158). The present investigation reports the production of resistance to paludrine (proguanil) in a strain of *P. vivax*. The patients were undergoing malarial therapy and the strain, which had not previously been in contact with paludrine, was maintained by blood inoculation. Two series of infected patients were treated with small doses of the drug. In the first series, 17 in number,

subinoculations from each patient were performed before drug treatment while in the second series repeated small doses of paludrine were generally given before subinoculation from that patient. The minimum effective dose of drug which would terminate fever and parasitaemia within a fixed time was established as 1.25 mgm. daily on three consecutive days. Resistance to therapeutic doses became apparent only towards the end of the observation period of 20 months during which 28 passages were made. At the end of that time it was approximately 80-fold in so far as three daily doses of 100 mgm. on successive days did not appear to influence fever or parasitaemia, although a dose three times as large did so. At the 23rd passage the strain was transmitted by mosquito and retained its resistant character. From their experience the authors conclude that there is little chance of producing resistant strains of the parasite by the clinical treatment usually employed. J. D. Fallon

PENIDO, H. M. DE SOUZA, F. F. & BEZERRA, F. P. G. Jr. Estudos sobre a ação de nova droga antimalárica no Vale do Rio Doce. [Study of the Activity of New Antimalarial Drugs in the Doce Valley] *Rev. Sem. Especial de Saúde Pública* Rio de Janeiro, 1948, July 12, No. 1: 27-34. 1 map. English summary (7 lines).

This preliminary study was designed to compare the efficacy of four new antimalarial drugs, each given in a single dose in the treatment of acute attacks of malaria in patients living in eight localities in the valley of the Doce River. In many of these places cases of malaria were few in number: the houses had recently been sprayed with DDT.

The four drugs tested were carmoquin, chloroquine, oxychloroquine and paludrine. For patients 15 years of age and over the dose of the drug administered was 1.0 gm. The total number of patients treated were coming in: 109 chloroquine 11 oxychloroquine 12 paludrine 33. Parasites were found in 87 of the patients: *P. falciparum* 43 *P. vivax* 37 *P. malariae* 4 mixed infection 3.

There were no symptoms of intolerance with any of the four drugs. Carmoquin was very effective. Paludrine gave the poorest results. Of 17 patients treated with paludrine 5 continued to show parasites in the peripheral blood 7 hours after the administration of the drug. These five patients were all in the group 1-4: they had each received only 0.25 gm. paludrine. Newman H. Kil

CHAUDHURI, R. N., RAI CHAUDHURI, M. N. & CHAKRABARTY, N. K. Chloroquine (BN 7618) in Malaria. *Indian J. Malariology* 1948 Mar-June 2, No. 1: 2, 12, 5 charts & figs.

Fifty patients with active malarial infection were treated with chloroquine in the Carmichael Hospital, Calcutta. Eighteen had *P. falciparum* 7 *P. vivax* 1 *P. malariae* and 4 mixed *P. vivax* and *P. falciparum* infection. The drug was given in tablet form each tablet containing 0.25 gm. of the base. Some patients received two tablets at the first dose, another tablet after six hours and then one tablet on each of the two following days—five tablets in all. The remaining patients each received a single dose of 1 x tablet. The above are doses for adults. The temperature fell to normal in an average period of 28.8 hours with the first treatment and 4.9 hours with the second. Asexual parasites disappeared within 35 hours with the first treatment and 25.5 hours with the second. These results were more prompt than those obtained with either quinine or quinine sulphate or paludrine. Symptomatic reactions were noted in 4 patients.

insomnia (4 cases), gastro-intestinal irritation (1 case), pruritus (3 cases), and pain in the lower abdomen, genitals and thighs (1 case) Gametocytes were apparently unaffected by treatment

EJERCITO, A & DUQUE, M Preliminary Report on Cam-AQI Dihydrochloride (Miaquin, Camoquin) in the Treatment of Human Malaria *J Philippine Med Ass* 1948, Nov, v 24, No 11, 633-42

This paper reports the results of the first trials of the treatment of malaria with CAM-AQI to be carried out in the Philippines. Each patient treated received a single curative dose, the main object of the inquiry being to determine the suitability of the drug for treatment of malaria in the field. Each adult patient received 8 tablets, 0.4 gm, of CAM-AQI. In all 128 patients were so treated, 84 with *P vivax* and 44 with *P falciparum* infections. *P vivax* parasites and fever were absent on the 3rd or 4th day in most cases, in afebrile cases the parasites had disappeared on the 2nd day. Fever in *P falciparum* infections persisted from 3 to 5 days, schizonts disappeared from the blood in from 2 to 4 days. The drug had no apparent effect on crescents. No symptom of drug intolerance was ever noted. Only 9 of the *P vivax* patients and 1 *P falciparum* patient suffered relapse after treatment, the periods of observation are not stated

JANG, Chang-shaw Present Status of Studies on Chinese Antimalarial Drugs. *Chinese Med J* Chengtu Edition 1945, Apr, v 63A, No 3, 126-30

Shortage of quinine and of synthetic malaria remedies during the war stimulated interest in indigenous remedies in China

Sinine, an alkaloidal substance obtained from the root bark of an ash tree, *Fraxinus mallacophyla*, which grows in the south-west of Yunnan, was tried and found wanting. For centuries past the bark has been used as a febrifuge.

Fravin, a glucoside obtained from the bark of *Fraxinus chinensis*, was tried in the treatment of eight patients with *P vivax* malaria. The author found it to be devoid of antimalarial properties.

Ch'ang Shan has been credited with antimalarial properties for 4,000 years. The botanical identity of the original Ch'ang Shan appears to be a matter of some doubt. The name is now applied to a herb, *Dichroa febrifuga*. An extract containing water-soluble substances from the root was given to thirteen patients with *P vivax* malaria. The results were stated to be comparable to those obtained with quinine in similar cases. Two alkaloids have been isolated from Ch'ang Shan, further chemotherapeutic studies were being made [see also this *Bulletin*, 1948, v 45, 755]

RAY, A. P. Prophylactic Use of Paludrine in a Tea Estate. *Indian J. Malariology* 1948 Mar-June v. 2 Nos. 1/2, 35-46 4 graphs. [17 refs.]

The observations recorded were made in a Tea Estate in a hyperendemic malarious region of North Bengal. The labour force numbered about 700 including 800 children. The vector is *A. sinensis*. Prophylactic medication began on April 16 and was continued till October 29 1947. A single weekly dose of paludrine, 3 tablets (0.3 gm.) was given to 338 persons. 1 tablet (0.1 gm.) of paludrine was given twice weekly to 889 persons. 1 tablet of chloroquine (0.25 gm. base) was given once a week to 287 persons.

There was a remarkable decline in the incidence of fever cases during the period of drug administration. The number of cases recorded from April to October in each of the years 1941 to 1947 was 1941 1974 1942 1064 1943 3022 1944 2834 1945 3818 1946 2794 1947 158. Among the 158 cases of fever recorded in 1947 there were only 17 cases of proved malaria among 1750 adults who had been placed on prophylactic treatment. Attendance registers showed that all but one of these 17 patients had taken the treatment irregularly. Only one case was considered to be a genuine breakthrough.

The total death rate for 1947 was 18.6 as compared with 32.77 per thousand for 1946. The birth rate in 1947 was 39.3 as compared with 13.8 per thousand in 1946 and the infant mortality rate 171.05 as compared with 200.4 per thousand live birth in 1946. There was a marked improvement in the health and efficiency of the labour force.

VERMA, P. K. D.

KLOPPER, G. STOR, D. & OTT, L. A. D. Een onderzoek naar de suppressieve werking van paludrin bij malaria tertiana. [The Suppressive Action of Paludrine in Benign Tertian Malaria.] *Nederl. Tijdschr. Geneesk.* 1948 Nov. 27 v. 92 (n) No. 48 3922-9 4 figs. English summary (6 lines).

The effect of weekly paludrine therapy on the prevention of benign tertian malaria were investigated in a large number of persons. In doses of 100 mgm. a week for adults and 50 mgm. in children paludrine appeared to take off the clinical attack. In persons with a tendency to relapse paludrine in these doses appeared to suppress such a relapse.

P. MANSION HARR

SMITH, H. F., DE, F. J. & CABRERA, D. J. Studies on the Efficiency of Chloroquine and Chlorguanide as Antimalarials: I. As Suppressants. Reprinted from *Acta Mal. Philippina* 1948 Oct. Dec. 5 v. 16 pp. [12 refs.]

This study of the relative suppressive value of two antimalarial drugs was carried out simultaneously in two places in the Philippines among lumbermen and their families in an isolated valley 1,200 feet above sea level in the island of Luzon, and in a settlement on a plateau about 900 feet above sea level in Negros Occidental. Both localities have well-defined wet and dry seasons and in both abundant streams are prolific breeding grounds for *Anopheles* *farinosus*, the vector. Parasite and spleen surveys were made prior to the experiment. In both places the population was divided into three groups comparable to each other with regard to previous infection, spleen size, age and sex. Group I received chloroquine, Group II chlorguanide (paludrine), Group III received sodium bicarbonate as a placebo. Adults were each given two 0.25 gm. tablets of chloroquine or two 0.1 gm. tablets of paludrine or two tablets of 0.3 gm. sodium bicarbonate once a week. The administration was continued for 40 weeks.

Among 125 persons receiving chloroquine, 2 developed overt malaria of 104 receiving paludrine, 17 developed overt malaria of 106 receiving sodium bicarbonate, 54 developed overt malaria. Chloroquine appeared to be responsible for nausea and vomiting in two patients, vertigo in one, and flatulence in one patient.

With the doses used chloroquine was a more efficient suppressive agent than was paludrine

Norman White

WALLACE, R. B. Insecticides and *A. maculatus*. *Med J Malaya* 1948, Sept., v 3, No 1, 5-33, 1 plan & 8 charts

On a rubber estate in Malaya of over 10,000 acres in typical *Anopheles maculatus* country, pre-war methods of control of hyperendemic malaria by anti-larval measures had proved unsuccessful and were replaced by a reliance on drug prophylaxis with atebrin [mepacrine], post-war atebrin was in turn replaced by paludrine. The mosquito nuisance, however, remains and demands alleviation. If residual insecticides could be proved to be effective it was hoped that the mosquito population would be reduced to the extent of preventing the annual epidemic of malaria and, indeed, that, in combination with the power of paludrine to prevent the fertilized female gametocyte developing to the sporozoite stage in the mosquito, a diminution in general incidence of malaria would occur.

Incessant biting of employees by bed-bugs and mosquitoes led to a trial of eight insecticides, four of which contained DDT, two Gammexane and two "Technical Chlordane".

Preliminary trials with 5 per cent DDT in kerosene and with Gammexane dust in 1947 during the sixteen-week *A. maculatus* season gave "the impression that *A. maculatus* adults were completely eliminated from the lines", yet there was "no apparent effect on the breeding places nor on the malaria rate."

In the 1948 season, tests were conducted on the eight insecticides and the following entomological methods were used to assess the effects —

- (a) Weekly morning (5 a.m. till dawn) catches in dwellings
- (b) In one room only night (8 p.m. till midnight) catches of mosquitoes (i) caught in the act of biting, and (ii) engorged and resting on the wall or dead on sheets on the floor
- (c) Catches in untreated cattle sheds at the same periods
- (d) Catches in untreated control rooms at the same periods
- (e) Observations on breeding places

The insecticides were applied at fortnightly intervals [precise dosage is not stated] during the *A. maculatus* season. Under laboratory conditions all the insecticides were lethal to mosquitoes; none prevented *A. maculatus* entering rooms and feeding; all reduced the early morning catches in varying degree, some to nil without any evidence of dead mosquitoes. An irritant effect is ascribed to the DDT group affecting both morning and evening catches. Larval density in breeding places and the malaria rate were not affected. The author concludes that "There is still no proof that it [DDT] is the most effective insecticide against *A. n. maculatus*" though presumably the best of this series.

These observations are comparable with those of Muirhead Thomson concerning the effect of DDT on *A. gambiae* in Africa thus *Bulletin* 1949, v 46, 439, the entomological methods used by the latter had a higher degree of accuracy. The Gammexane preparation used in Malaya was not the recent water-dispersible powder P 530 (now P 520) tested in East Africa with favourable results.]

R. Ford Tredre

DOWNS W. G. COLORADO IRIS R. & GARAN J. B. Residual Effectiveness of DDT in the Third Season after Application. *Amer J Trop Med* 1948 Sep. v 28 No 5 741-5

The mud brick houses in an area of Mexico where *A. gambiae* is prevalent were treated with DDT in 1945 the dose being 190 mgm. per sq. ft. (6.7 ounces per 1,000 sq. ft.). An identical collecting procedure was followed before and after treatment with the following results—

Date	No. of collections	Average mosquitoes per building	
		Treated buildings	Untreated buildings
1945			
Before treatment	3	12	9
After treatment	11	0.003	59
1946	4	0.75	18
1947	4	1.35	14.8

The presence of DDT two and a half years after application was shown by biological and chemical tests. G. Macdonald

MORRISON D. B. & JESKES H. A. Alterations in some Constituents of the Monkey Erythrocyte Infected with *Plasmodium knowlesi* as related to Pigment Formation. *J. National Malaria Soc.* 1948, Dec., v 7 No. 4 259-64 3 figs.

Assuming that the parasite pigment is derived quantitatively from the host erythrocyte haemoglobin and that the total erythrocyte haematin is constant the authors calculated total erythrocyte concentration in given samples of blood (monkey and duck) by measuring the total haematin and the average effective number of pigmented parasites (*P. knowlesi* and *P. l. m. l.*) by determining the parasite haematin. Alteration in parasitized cell of total % total lipids and total solids were also determined in relation to the amount of parasite haematin present.

In *P. knowlesi* malaria in *Macaca mulatta* they found that 0.76 per cent of haemoglobin was converted to parasite haematin when 1.0 per cent of erythrocytes were parasitized with the average pigmented form of parasite. This result compared favourably with that of BULL *et al.* (*Phil. Mag.* 1949 v 40, 117) who found in two monkeys infected with *P. k. m. l.* that 40 per cent total haematin existed as free haematin when there was 58 per cent infection of erythrocytes and 49 per cent as free haematin when there was a 67 per cent infection. These figures correspond to 0.72 and 0.79 per cent of haemoglobin being metabolized to parasite haematin in a 1.0 per cent infection.

The authors conclude that 78 per cent of host cell haemoglobin in *P. k. m. l.* infections in *M. mulatta* is converted into parasite pigment by an average pigmented form of parasite. Total % and total solids of the erythrocyte are reduced but there is an increase in total lipids. These changes presumably being brought about by parasite metabolism. B. G. Macdonald

HENDERSON F. G. ROSE C. L. HARRIS P. N. & CHEN H. K. Dichroins the Antimalarial Alkaloid of Chang Shan. *J. Pharm. & Exp. Ther.* 1949 Feb. v 93 No. 1 191-200 3 figs. 24 refs.

In the search for new antimalarials during the late war attention was drawn to Chang Shan, the root of an indigenous evergreen shrub of SW

China, much prized for its antimalarial properties there. The botanical name of the plant is now generally accepted as *Dichroa febrifuga* [For recent developments on the chemistry of the active principles present see this *Bulletin*, 1946, v 43, 1012, 1947, v 44, 699, 964, 1948, v 45, 578 and above, p 611] Substances have been obtained from the plant more active than quinine in *P. lophurae* infection of ducks and in *P. gallinaceum* infection of chickens. In China, one alkaloid isolated was named γ -dichroine (believed to be a quinazoline derivative), a crystalline substance of m.p. 160°C. In the present investigation this substance has been tested for antimalarial and other properties, in ducks infected with *P. lophurae* and canaries infected with *P. relictum*, determination of the median suppressive dose (SD50), that which reduces parasitaemia to half, in the case of γ -dichroine and quinine, showed that the former was very much more active. The new substance surprisingly proved more toxic to mice when given orally than by the intravenous route, and in lethal doses damage was done mainly to the liver. In pigeons the alkaloid had an emetic action as sometimes seen in man. Blood pressure and respiration in anaesthetized dogs was unaffected and intestinal peristalsis was stimulated. In unanaesthetized animals there was diarrhoea. In certain doses intravenous administration caused hyperglycaemia in rabbits. The drug also exerted an antipyretic effect.

- 1 WINGSTRAND, K. G. On some Haematozoa of Swedish Birds with Remarks on the Schizogony of *Leucocytozoon sakharoffi*. *Kungl. Svenska Vetenskapsakad. Handl.* Stockholm 1947, v 24, No 5, 31 pp., 19 figs. [34 refs.]

- 11 — Further Studies on *Leucocytozoon sakharoffi*. *Ibid.* No 8, 17 pp., 12 figs. [11 refs.]

1. A description is given of six species of *Leucocytozoon* including a new unnamed one in a rook, and of two species of *Haemoproteus*, including a new one, *H. buteonis* in a buzzard. The endocrine glands of two young crows (*Corvus corone cornix*) showed the presence of the asexual forms of *Leucocytozoon*, viz. very striking megaloschizonts. They were found in the anterior and posterior portions of the pituitary gland, in a testicle, and in the thyroid. The youngest schizonts appear to develop in endothelial cells of capillaries. The young schizont is composed of a few "cytomeres," 2-3 μ in diameter, and each cytomere is surrounded by a vacuole. The nucleus of the host cell enlarges as does the cell itself. Eventually the diameter of the nucleus is enlarged 40 times, the cell itself measuring 470 μ . In these later stages, the cytomeres form a continuous layer around the nucleus, each is about 15 μ in diameter and contains numerous merozoites visible as deeply staining granules 1 μ in size. A zone of cytoplasm free from cytomeres surrounds the host cell nucleus. In adult birds this type of schizont was absent, a smaller kind in the hepatic parenchyma is described but whether the latter structures are truly parasitic even the author appears to doubt.

11. Material additional to that described above was examined in the organs of two half-grown crow nestlings which had suffered from very violent attacks of the disease (about 10 infected lymphocytes to 100 erythrocytes). The course of development of the megaloschizonts was observed in the spleen where they occurred in abundance. The host cell appears to be a macrophage. Development is described all in terms of the "cytomere." The cytomeres split up into "sub-cytomeres" bladder-like bodies with the granules concentrated on the surface. Eventually, all differentiation is lost and a continuous mass of merozoites is formed outside the host cell nucleus. The merozoites exhibit bipolar staining. The ripe schizont bursts and discharges a cloud of merozoites into

the adjacent blood vessel. The granules give a positive Feulgen reaction only in the final stages—earlier the usual Romanowsky or haematoxylin stains fail to show any chromatin. This substance, however, can be impregnated with silver by using the Bodian technique and then is visible throughout the cycle.

[These observations confirm Hirst's work (*J. Infect. Dis.* 1942, v 71 18) on another species of *Leucocytozoon*. The megalo-schizont of the Swedish parasite, however, appear to be five times the size of the American ones, reaching nearly half a millimetre in diameter. In size therefore they form a link between the schizonts of *L. simonsi* and the 2 mm. merocytes of *Hepato-cyclus kochi* this *Bulletin* 1948, v 45 683. In the latter the host cell becomes similarly enormously enlarged but the nucleus undergoes repeated divisions instead of growing into a body 190 μ in diameter. The final product is alike in all three parasites, viz. a compressed mass of innumerable bipolar staining merozoites which escape into the blood to form gametocytes.]

P. C. C. GARHAM

HART, J. W. Observations on Blood Parasites of Birds in South Carolina. *J. Parasitology* 1949 Feb v 35 N 1 79-82.

The birds of a district in South Carolina, U.S.A. were examined in winter and summer for the presence of parasites in the blood. 4.9 per cent. showed infections in the winter and 1.6 per cent. in the summer. The following parasites were found: *Plasmodium circumflexum longatum brumpti* and *ridgwayi*, *Haemaphysalis leucorhynchos*, *Trypanosoma* and *Toxoplasma*. The majority of the birds were English sparrows (*Passer domesticus*). Sporozoite rates in the local *Anopheles* have been high, although human malaria cases were uncommon; the possibility of an avian origin had, therefore, to be considered, and these observations provide some evidence that such an origin may have existed.

BLACKWATER FEVER

WEISE, W. Ueber das Pseudo-Methämoglobin (Methaemalbumin) N. II. Fairley. Pseudo-Methaemoglobin (Methaemalbumin) Fairley. Reprinted from *Deutsch. Tierärztl. Wochenschr.* 1941 v 45 No. 7 118-24. 17 ref.

FAIRLEY's demonstration of the rapid development of methaemalbumin on the addition of an alkaline solution of haematin to plasma and heating to 40 C. (this *Bulletin* 1935 32 210 1937 34 84) impressed the author that methaemalbumin is really only haematin dissolved in serum and not the firm chemical compound of haematin and crystallinum that Fairley claimed. The author considers the production of haemochromogen after the addition of concentrated ammonium sulphide in Fairley's blackwater fever cases a proof of this. Since Schumm regarded this reaction as evidence of the presence of haematin (Fairley on the other hand believes Schumm's reaction indicates the presence of the pigment methaemalbumin and not haematin).

The argument in this paper covers much the same ground as Fairley's original communication. The author points out that Schumm's test only

distinguishes haematin from methaemoglobin and that haematin (as indicated by the test) has been found in the blood serum in many pathological conditions, including severe malignant tertian malaria. He confirms HEILMEYER's observation that the spectrum of haematin dissolved in serum differs from that of alkaline watery haematin solution because it is combined with serum protein. In his view this combination is a loose one similar to other physiological combinations of substances with protein, for example "haemolytic" bilirubin. Fairley's pigment need not therefore be regarded as a firm chemical compound, in spite of its behaviour in the ultra-centrifuge or under electrophoresis. The production of haemalbumin on the addition of sodium hydrosulphite to methaemalbumin, as reported by Fairley, he regards as requiring further proof.

He confirms Fairley's observations on the slow production of methaemalbumin in mixtures of the haemoglobin and serum of mammals other than the human being and the ape, and reports his findings in a small series of experiments in which human, dog, rabbit and horse haemoglobins are compared in this respect. After 48 hours' incubation at 37°C the mixtures of haemoglobin and sera all produced methaemoglobin, small amounts in the human mixtures much larger in the others. On the other hand, "haematin" (as estimated by Schumm's test) was produced only in the human and dog mixtures. He suggests that this is because only easily split haemoglobins (such as human and dog) will give rise to haematin in serum. Other more resistant haemoglobins produce methaemoglobin only.

[The physiological and pathological importance of Fairley's observations with regard to methaemalbumin seems to the reviewer to be unaffected by this communication.]

KHO LIEN KENG Gestoorte nierfunctie bij zwartwaterkoorts [Disturbed Kidney Function in Blackwater Fever] *Med Maandblad Batavia* 1949, Feb 1, v 2, No 2, 46-51 [29 refs]

The English summary appended to the paper is as follows —

"Three cases of blackwater fever with renal damage are reported. The first patient showed during a week after disappearance of the clinical symptoms, an isosthenuria at a rather normal diuresis. The second patient died anuric.

"The third one produced symptoms of glomerulonephritis after a second attack of blackwater fever. Follow up a year later still showed renal insufficiency (blood-urea 1.078 g/liter, specific gravity of urine 1.004)."

TRYPANOSOMIASIS

VANDERPLANK, F L Studies of the Behaviour of the Tsetse-Fly, *Glossina pallidipes*, in the Field Influence of Climatic Factors on Activity *J Animal Ecology* 1948 Nov, v 17, No 2, 245-60 [17 refs]

The author wishes to investigate the relation between the activity of a tsetse fly, *Glossina pallidipes*, and certain climatic factors. His method, in broad terms, is to tie up an ox and catch the flies that come to it, recording them in fifteen-minute spells throughout the day. At the same intervals he measures temperature, humidity, light and so forth. Conditions for this type of experiment seem to have been good for there is some indication that the tsetse population did not vary greatly over a number of months. If, therefore, differences in the numbers of flies caught were established they were due to differences

in activity one might reasonably try to relate them to climatic factors. Had there been large differences also in the population this work would have been very difficult.

A point of considerable interest is that for several of the physical factors middle values are associated with greater activity of the fly than either high or low values. For instance within the limits of the conditions prevailing where the work was done the insect became more active the brighter the light but only up to a certain point. At midday on bright days the light was too intense and reduced the activity of the flies. The same was true both of humidity (measured by saturation deficiency) and of temperature. In each case there was a critical value above which the activity decreased. For instance for temperatures up to 29°C there was a positive correlation between the dryness of the air and the activity of the insect. But from 30°C upwards the correlation was reversed and became negative so that at the higher temperatures the drier the air the less was the activity of *C. fallax* flies. Throughout the paper full use is made of statistical methods and measures of significance are given.

There is an interesting comparison between the catch of *C. fallax* flies at different hours of the day in the thicket and out on the open hard pan. In the thicket perhaps because the temperature never gets very high and the light at midday is not very bright the insect is active all through the day, indeed equally active all through the day. But outside on the hard pan, there is a great reduction of activity at noon and soon after, except on days when much light is absorbed by dust in the atmosphere or by cloud. It is a matter of some interest that figures collected by other authors in Italian Somaliland and Zululand can on the whole be reconciled with this author's own figures from Tanganyika.

In this paper the author makes use of several modern conceptions about tsetse populations and advances our knowledge of his side of the subject considerably. One might perhaps say that not every point in the argument is equally well established; the reviewer believes that there is one serious statistical misprint which it is not possible for the reader to correct. P. 4 Bottom.

MORRIS K. R. S. & MORRIS M. G. The Use of Traps against Tsetse in West Africa. *Bull. Entom. Res.* 1949 Mar. v. 39 Pt. 4 491-528 5 text figs. & 8 pls. on 2 pls. 16 ref.

The authors describe their work in the Savannah country in the north of the Gold Coast where *Glossina fuscipes* and *C. luckhowskii* are common along river sides. They have not only attempted control by trapping but they have tried to understand the underlying principles. The result is that the paper tells one something about the fly-view of the world and advances our knowledge of the subject considerably. The problem is practical but the authors have not limited themselves solely to practical considerations.

Morris and Morris have tested a number of recognized types of tsetse traps and have developed one which they describe as the Animal Trap. It seems to be a Harris trap but much smaller indeed about the size of a great fly netter incidentally that it is implied that loop and gill are commonly fed upon by these insects which we think not the experience in some other parts of Africa. Under their conditions the animal trap is the most efficient among several types tested. In addition to comparing the effects of different types of trap the authors have described much about the fly, comparing their Animal traps with tsetse fly nets which are well known to be no trap at all. Forward comparison is possible in the case of the trap and perhaps of the fly in its carrying with tsetse. They end their paper by stating that the exact position

in which one places the trap is very important it should be sited in an open feeding ground frequented either by man or animals. If it is placed close to an actual tethered animal, it catches more flies than if it is not.

Much of the authors' work has been done in small "sacred groves" where clearing is not possible for religious reasons. In these groves they have used traps at a density as high as twenty to the acre, but they still find that eradication of tsetse by trapping is not possible. Traps may, however, prove valuable to protect man from fly or sleeping sickness because they will catch a large proportion of the flies, perhaps quite quickly. Moreover the catch is highest in the dry season, when the contact between man and fly is likely to be closest because there are very few water holes and those generally in fly belts.

P. A. BURTON

MORRIS H. R. S. & MORRIS M. G. The Use of Traps against Tsetse in West Africa. *Bull. Entom. Res.* 1949 Mar. v. 39 Pt. 4 491-528 5 text figs & 8 figs in pls. 16 r. 6s.]

The authors describe their work in the Kaolakh country on the north of the Gold Coast where *Simulium felse* and *G. tachinoides* are common along river sides. They have not only attempted control by trapping but they have tried to understand the underlying principles. The result is that the paper tells us something about the fly, new to the world and advances our knowledge of the subject considerably. The problem is practical but the authors have not limited themselves solely to practical considerations.

Morris and Morris have tested a number of recognized types of tsetse traps and have developed one which they describe as the Animal Trap. It resembles a Harman trap but is much smaller indeed about the size of a goat. One notes incidentally that it is supposed that sheep and goats are commonly fed upon by these insects which we think is a little experience in some other parts of Africa. Under their conditions the animal trap is the most efficient among several types tested. In addition to comparing the efficiency of different types of trap the authors have devoted much thought to comparing their Animal traps with teams of flies which work in the same area, no straight forward comparison is possible the activity of the trap and perhaps of the fly both varying with season. They find a rather large difference in the

of these gave a positive complement fixation, 190 did not. In 62 the xeno-diagnostic test was carried out [whether from the positive, or negative, or both is not stated] and in five the result was positive. In all those studied similar tests were made—histories, symptoms, physical signs and electrocardiographic findings. The last is the most important from the point of view of this investigation. Among 104 of the 122 giving a positive complement fixation, 34 showed electrocardiographic changes (32.5 per cent), among 176 negative to complement fixation six only showed changes (3.5 per cent). The commonest of these disturbances was premature ventricular contractions and close behind came right bundle branch block and atypical QRS or T wave abnormalities, other lesions observed were prolonged P-R interval and a certain degree of, even up to complete, A-V block.

Other causes of chronic cardiac disease were looked for and in 29 of the 34 patients no other cause could be found, the remaining five had syphilis also, which might account for aortic disease and arteriosclerotic changes. Four of the former died within a year of the observations being made.

LEISHMANIASIS

KIRK, R. *The Differentiation and Nomenclature of Leishmania*. *Parasitology* 1949, Feb., v 39, Nos 3/4, 263-73 [119 refs.]

This paper is itself a review and therefore should be read in the original as it is not possible to condense the contents except in the most general way, which has been attempted here.

An account is given of the early history of the discovery of parasites of the genus *Leishmania*. This is followed by sections dealing with the differentiation of "species" of the genus, based on various grounds, morphological, clinical, serological and otherwise, which are shortly considered below.

Differentiation based on morphology

The comparison of various strains of *Leishmania*, both cultural and in the Leishman-Donovan-body form, have led some workers to consider that differentiation is possible on grounds of size between *L. donovani* and *L. tropica*, while others have distinguished these species by the type of growth in Noller's medium. Still other workers, however, have failed to confirm these distinctions.

Differentiation on clinical and epidemiological grounds

These have been the main grounds on which leishmanial species have been separated, even though they are unsatisfactory from the systematist's point of view. After creation of the genus *Leishmania* for the parasite of Indian kala azar other species were differentiated as similar parasites were discovered to be the aetiological agents in other clinical conditions such as dermal ulcers occurring in the Old and New Worlds (*L. tropica* and *L. brasiliensis*). Further creations were *L. infantum*, *L. nitroica*, *L. peruviana* and others.

Differentiation by results of animal inoculation

The results obtained in this way have been contradictory and inconclusive. *Leishmania donovani*, the parasite of kala azar, may give rise to cutaneous lesions in experimental animals, while *L. tropica*, the parasite of oriental sore, may produce generalized infections. In these cases, again, no uniform results are obtained and the results of infection vary greatly in different strains of the same "species". Similar attempts to differentiate *L. chagasi* of South America from *L. donovani* by animal inoculations fail to pass the test of adequate experimentation.

Of the mammals mentioned sixteen were examined in the laboratory by xenodiagnosis. Four animals proved to be infected but no trypanosomes were found in the blood nor did the tissues at post mortem reveal any parasites [One presumes that the insects used were clean laboratory-bred individuals but it is not stated].

An account is given of various laboratory animals infected experimentally by the various strains of *T. cruzi* coming from reduviid bugs from various localities in the area under survey.

The results obtained included the demonstration of "Leishmania" bodies in muscular tissue.

The usefulness of xenodiagnosis in the detection of naturally-occurring infections is emphasized.

H. F. SAWH

PEREGRINO J. & BERNOTCHIK M. Inquérito sobre doença de Chagas no Hospital da Santa Casa de Misericórdia de Belo Horizonte (Mina Gerais, Brasil) [Cases of Chagas's Disease among Patients in a Hospital in Minas Gerais, Brazil.] *Brasil-Medico* 1948 Sept 4-11 v. 62 Nos 30-37 314-15 English summary

This short article appears to be a part of a fuller work, which, when complete is to form one of the publications issuing from the Oswaldo Cruz. In this it is a summary of results obtained from examining 181 unselected patients at the Santa Casa de Misericórdia Hospital in Belo Horizonte. The examination was thorough and included general physical examination, electrocardiograms, complement fixation with *T. cruzi* culture antigen and any suspicious patient was further subjected to xenodiagnosis and X-ray tests.

Thirty-seven presented indications of infection with *T. cruzi* of 49 with cardiac disturbance 18 were due to Chagas disease, which accounted for six. Of these 18 the majority showed changes in the right bundle of His and of QRS auriculo-ventricular blocks. Just half of those with chronic heart disease due to *T. cruzi* were under 30 years of age whereas four-fifths of those with heart lesions of other origin were over that age. On the whole the complement fixation test was a valuable method of diagnosis (in 31 out of 77 cases) but only eight of the 41 gave a positive result to xenodiagnosis test.

The chief vectors in Minas Gerais were *Triatoma dimidiata* and *T. sordida*. 12 other species of Triatomidae are found in the State but they are not active vectors. Triatomidae are found in 201 of the 316 municipalities of the State and infected persons were found in 143 municipalities. A chart has been drawn up showing the areas most highly infected.

H. H. J. S. GILL

DIAS E. LARA J. L. S. & PEREGRINO J. F. Estudo de uma importância social da doença de Chagas. I. Inquérito epidemiológico feito nas circunstâncias de Bambuí, Oeste de Minas. Studies of the Social Importance of Chagas's Disease. I. Investigation carried out in the Environs of Bambuí, Western Minas Gerais. *Brasil-Medico* 1949 Nov 4-11 v. 63 Nos 45-51 & 53-61 13 English summary

The evidence afforded by this investigation demonstrates very clearly the large part which infection with *T. cruzi* plays in producing cardiac disease in this district at all events. Studies in other districts will have to be made to see whether this applies in them also.

The authors examined persons engaged in the railways including members of their families altogether 312 individuals. One hundred and twenty-two

re 7 species of *Phlebotomus* in Colombia, namely *P. squamiventris*, *evansi*, *anamensis*, *monticolus* var *incanum*, *colombianus*, *osornoi* and *longipalpis*. The dog is probably the reservoir host and inoculation of dogs with human material produces lesions identical with the human disease and the sera of dogs with visceral localization give the same results as human sera. But the question of the dog being definitely the reservoir host is not yet proved, though no other animal seems to be likely.

For treatment the author uses diphosphate of chloroquinoline [chloroquine]. In solution this is stable at pH 4-6.5 and withstands a temperature of 21°C for 40 minutes, above pH 6.5 it decomposes. It is a white crystalline powder, with acrid, bitter taste. After experimental tests on rats, rabbits, dogs and monkeys the author tried the drug in human patients in the following doses *per os*. For very serious cases with extensive lesions, multiple and with perforation of the nasal septum, first day, 1 gm at 8 a.m., 0.5 gm at 3 p.m., second day, 0.5 gm at 8 a.m. and 3 p.m., third day, 0.5 gm at 8 a.m. and 0.25 gm at 3 p.m., altogether 3.25 gm. In cases of less severity, the dosage for the first day is the same, but on the two following days 0.5 gm at 8 a.m. only, a total of 2.5 gm.

Twenty-one patients have had this treatment, 10 are completely cured and their lesions cicatrized, 3 are much improved with diminution of the lesions, less secretion, less itching and local pain, 3 others had improved markedly when they left and could not be followed up. 3 more are at present under treatment and "show appreciable improvement", 2 have not responded to the treatment.

The author concludes that the results of this new treatment by oral administration of diphosphate of chloroquine are better than those from any of the drugs hitherto used, the toxicity is low in contrast with the antimonials, it is given *per os* and patients can be up and about and the cost is less than that of drugs previously used. [The doses of chloroquine appear to be high, compared with standard doses, used in the treatment of malaria.]

H. Harold Scott

FEVERS OF THE TYPHUS GROUP

WEYER F. Vergleichende Untersuchungen an Rickettsien [Investigations into the Relationships of the Rickettsiae]. Reprinted from *Ztschr. f. Naturforsch.* 1947, v. 2b, Nos. 9/10, 349-58. [14 refs.]

For four years the author has been investigating the rickettsiae of the louse-typhus (*Läusefleckfieber*) and flea-typhus (*Flohstreckfieber*) groups. Details of the studies, including the technical methods employed, are given in other recent papers [see also this *Bulletin*, 1949, v. 46, 537 and below].

The present paper consists chiefly of a long discussion of the remarkable variations observed in the habit of growth and virulence of *Rickettsia prowazekii* and *R. mooseri*, both of which in laboratory conditions have often been observed to become extracellular and at the same time non-virulent for lice and mice. The modified types may even be indistinguishable from the rickettsiae which are naturally extracellular and non-virulent for mice, viz., *R. uolynica*, *R. pediculi*, and *R. weigli*.

Cross immunity tests

Without going into details of the results of cross immunity experiments cited, it may be said that here also there is a lack of agreement in the results obtained by various workers. Thus some writers maintain that a previous infection with *L. donovani* confers immunity against *L. tropica* but others have been unable to confirm this.

Serological Tests

These have comprised attempts to produce specific agglutinating sera, complement fixation tests, the Ruckenberg (adhesion) phenomenon and other techniques. Results by different workers have been contradictory and inconclusive in so far as the differentiation of "species" by these means is concerned and the impression gained by experienced workers is that the clear-cut results originally claimed when a few strains only were studied experimentally become obscured when a larger number of strains is studied.

Veno-differentiation

This term has been coined to indicate the different behaviour of strains of *Leishmania* in different species of *Phlebotomus*. In a species of *Phlebotomus* which is the vector of a strain of *Leishmania* the parasites develop in the anterior station but at best there is not at present sufficient accurate information to make this an easy or definite means of separating strains.

The implications of the various studies mentioned above are discussed in relation to the morphological basis of zoological nomenclature and it is pointed out that the taxonomic status of biological races has not been defined by systematists. In spite of this it is considered justifiable to recognize three species of *Leishmania*: 1. *L. tropica*, 2. *L. donovani* and 3. *L. braziliensis* on account of the clinical differences exhibited in the infections caused by these parasites which have been under close observation for 50 years and has not changed their characters in spite of the innumerable parasitic generation which such a lapse of time implies. It is felt that such consistent behaviour implies corresponding biological differences in the parasites, which are hereditary and stable. The last section of the paper deals with the synonymy of the species of *Leishmania* occurring in man.

PUEZLO GARCIA, M. J. Leishmaniasis. [History of Leishmaniasis in Colombia.] *Rev. Facul. de Med. Bogotá* 1949 Jan v 17 N. 7 738-59

The first part of this article gives a sketch of the history of mucocutaneous leishmaniasis, locally known as *puerca* or *Marran* (literally, *poor* or *worse* but used as an adjective to anything foul or dirty in Colombia from the first published description of a case in a boy 11 years old in July 1900. In the early days it was regarded as either syphilitic or a suppurative, leprous lesion, and only at the end of the century were the differences noted between cutaneous leishmaniasis and cancer, scrofula, syphilis and other diseases. It was not until 1944 that a case was recognized by Dr. A. Gait Gal as such. The first case of visceral leishmaniasis in Colombia.

The author next notes the Colombian endemic foci of the disease and mentions nearly a score of them and then lists the possible transmission of the

- GIROUD, P & CIACCIO, G Inoculation de *Rickettsia prowazeki* et *mooseri* chez les poissons Contrôle sérologique et immunité provoquée [Inoculation of Fish with *Rickettsia prowazeki* and *R mooseri* Serological Results] *C R Soc Biol* 1948, Dec, v 142, Nos 23/24, 1478-9

The following is a translation of the authors' summary —

Different fish may be infected with rickettsiae of epidemic typhus and react with the formation of agglutinins The murine strain seems to be more adaptable than the epidemic At least two passages can be maintained with the two strains, through the gills or other organs The use of the liver or peritoneal organs, however, seems to be preferable

- MITTERMAIER, R Die Erkrankungen des Ohres beim Fleckfieber [Diseases of the Ears in Typhus Fever] *Deut med Woch* 1948, Mar 12, v 73, Nos 9/12, 109-11

The author discusses in general terms the various complications of typhus fever that are associated with the organs of hearing He believes that if all the minor degrees of deafness are included 80 per cent of the patients may suffer from auditory troubles He deals specially with septic infections of the middle ear, which usually appear about the 16th to the 18th day He estimates that as many as 15 per cent of patients with severe attacks may be affected, and he stresses the need for close observation of the patients with a view to early treatment of a complication which may have disastrous results

John W D Megaw

- PFEFFER, K H Über Störungen der vegetativen Regulationen in der Fleckfieberkonvaleszenz [Disturbances of the Sympathetic Regulating Mechanism in Typhus Convalescents] *Deut med Woch* 1948 Dec 3, v 73, Nos 45/46, 596-8, 3 charts

- GOOD N E & KOTCHER, E Murine Typhus Fever in Louisville, Kentucky *Pub Health Rep* Wash 1949, Feb 25, v 64, No 8, 229-37, 1 map

In the present study, sera of 793 inhabitants of Louisville, Kentucky, yielded only three complement-fixation reactions against murine antigen at a titre of 1-4 Sera of 351 rats yielded only one positive reaction at a titre of 1-8

In 27 per cent of the rats caught in the market and business areas of the city *X cheopis* were found

The findings did not tend to justify the suspicion that murine typhus had extended to a significant degree as far north as Louisville

- AKLE DELGADILLO, J & PÉREZ REBELO, R Existencia de tifo murino en Cd Camargo, Chihuahua, Rep Mex [The Presence of Murine Typhus in Camargo, Chihuahua] *Rev Inst Salubridad y Enfermedades Trop Mexico* 1948, Sept, v 9, No 3, 195-7

The English summary appended to the paper is as follows —

'1 350 Weil-Felix's tests were performed with human sera from Ciudad Camargo, Chihuahua, two of which were positives

'2 These two positives sera fixed the complement with antigen of murine, and not with that of classic typhus

'3 These results prove, first time, the presence of murine typhus in Ciudad Camargo, Chihuahua, Mex'

In several cases the modified types have reverted to the original type and have again become intracellular and virulent though it has not been found possible to devise a method by which the reversal can be produced with uniform success.

Among the conditions in which changes in type have occurred are — (1) the maintenance of strain by the customary laboratory method (2) intracoeleomic inoculation of ticks (3) transmission through ticks, flea and weevil larvae and (4) storage for long periods of dried infected faeces of arthropods.

The author states that both *R. prowazeki* and *R. m. neri* may be so variable in laboratory conditions that the differences observed among individual strains of either organism can be greater than the differences usually relied on to distinguish between the two species of rickettsiae.

It is regarded as an open question whether the changes are due to inherent mutability of the organisms or to the simultaneous occurrence of intracellular and extracellular types, one or other of which predominates when environmental conditions become favourable for its development.

[The possible bearing of the mutability of the rickettsiae on changes in virulence of typhus infection during epidemics and on the carrier of infection between epidemics is regarded as a subject for speculation.]

Complement fixation and mouse-protection tests might throw light on the question whether important qualitative changes have occurred in the antigenic and immunological properties of the modified strains of rickettsiae. Most of the changes in type seem to have occurred in very artificial conditions; this factor must be taken into account when attempting to assess the bearing of the findings on the problems of human typhus. Jah B. D. Meyer

WEYER F. Die künstliche Infektion von Zecken mit Rickettsien und anderen Krankheitserregern. [Artificial Inoculation of Ticks with Rickettsiae and other Disease Agents.] *Zeits. f. Rat. I. Med. Orig.* 1948 v. 152 449-57.

Various tick species, especially *Ornithodoros moubata* were successfully inoculated by the intracoeleomic route with suspension containing *Rickettsia m. neri*, *R. prowazeki* and *R. wolkyi* etc. The agent of atypical bronchopneumonia or benign bronchopneumonia (Hersberg) was also cultivated in the same way. [Apparently this was *R. burnetii* see this *Bullet.* 1949 48 511.]

Attempts were made without success to cultivate the virus of mouse bronchopneumonia and influenza. In the abstract in English the influenza virus is wrongly referred to as the 'Influenza bacillus'.

Technical details are given of a large number of these experiments.

Only one out of three attempts to cultivate *R. andersoni* was successful. In this case tick suspension made 60 days after inoculation was infective to mice by the intrarectal route.

Four out of five strains of *R. prowazeki* were cultivated in ticks. One pair was of which were found infective to mice as mice test made at intervals ranging from 14 to 28 days after inoculation. Two of the strains became extracellular and non-pathogenic for mice after passage through the tick but one of these resumed the intracellular habit of growth and virulent for mice after three passages through lice. The other remained extracellular and non-pathogenic to mice after isolation from the eggs of the uninfected tick and later passage through lice.

In 15 sets of experiments with *R. m. neri* 13 positive results were obtained. In some cases intracellular strains were used and several of these became extracellular and non-virulent for mice. In other cases extracellular strains became intracellular and regained their virulence. Jah B. D. Meyer

The methods of diagnosis included (1) intraperitoneal inoculation of mice with sputum of patients, (2) inoculation of mice with blood, (3) inoculation of guinea-pigs, followed by transfer through mice and ticks, (4) feeding of ticks, followed by transfer through mice, (5) feeding of lice followed by transfer through mice

Complement-fixation tests could not be carried out because enough antigen was not available, but there seems to be no doubt regarding the nature of the disease

The most likely mode of infection was thought to have been inhalation of infected dust

John W D Megaw

COMBIESCO, D & DUMITRESCO, N *Survie in vitro de Rickettsia burneti de la fièvre Q en Roumanie* [Survival in vitro of *Rickettsia burneti* in Rumania] *Ann Inst Pasteur* 1949, Jan, v 76, No 1, 79-80

A number of blood samples were collected from guinea-pigs infected with *Rickettsia burneti* isolated in Rumania, and after clotting were covered with a layer of a mixture of oil and vaseline. The samples were kept at room temperature and tested at intervals by guinea-pig inoculation. Typical febrile reactions were caused in animals tested up to eight months, and a mild reaction occurred in an animal tested nearly 300 days after the preparation of the sample. After 11 months the blood became laked though it was still free from bacterial contamination, it produced no definite reaction in the guinea-pig that was tested

COMBIESCO, D, COMBIESCO, Cornelia, DUMITRESCO, N, POPESCO, C & ZARNEA, G *Diagnostic rétrospectif par la réaction de fixation du complément d'un foyer roumain de fièvre Q* [Retrospective Diagnosis of Q Fever in Rumania by the Complement-Fixation Reaction] *Ann Inst Pasteur* 1949, Jan, v 76, No 1, 81-2

In March and April 1947, nine persons employed at the antirabic section of the Institute of Serology of Constanza, Rumania, were attacked by a fever which could not be diagnosed at the time. All the patients had been engaged two to three weeks before the onset, in one capacity or another, in shearing sheep which had come from the neighbouring area. Seven of the patients were attacked between March 28th and April 6th, the other two were attacked on April 11th and 23rd, respectively.

[The interest of the outbreak consists in its being the first to be recognized in Rumania, rather than in the retrospective diagnosis which was made by the complement-fixation test early in May, of the same year.]

WEYER F *Ueber Rickettsia wolhynica und die Diagnose des Wolhynischen Fiebers durch den Läuseversuch* [*Rickettsia wolhynica* and the Diagnosis of Trench Fever by the Louse Test] *Zent f Bakt* I Abt Orig 1948, v 152 403-14 [15 refs]

In 47 out of 146 cases of trench fever *R. wolhynica* was isolated from batches of lice which had been allowed to feed on the patients. In a number of cases the diagnosis could not have been made with certainty on clinical grounds. Scanty, yolk-sac cultures were obtained in some cases from suspensions of the infected lice and the cultures were sometimes infective for lice by intrarectal inoculation but it was not found possible to maintain the organisms by serial yolk-sac cultures.

SMADAL, J. E. JACKSON, Elizabeth B. LEY, H. L., Jr & LEWYTHWAITE, R. Comparison of Synthetic and Fermentation Chloramphenicol (Chloromycetin) in Rickettsial and Viral Infections. *Proc. Soc. Exper. Biol. & Med.* 1949 Feb 70 No 2, 191-4 2 figs. [11 refs.]

Chloromycetin formerly prepared only from the mould *Streptomyces rivecourtii* has recently been produced synthetically and has been found to have the same physical and antibacterial properties as the fermentation product. The synthetic drug has now been found by the authors to be as effective as the original type in prolonging the life of embryo chicks infected with *Rickettsia rickettsii*, *R. akari*, *R. mooseri*, *R. prowazekii*, *R. tsutsugamushi*, psittacosis virus and a strain of lymphogranuloma virus.

In two batches each of 8 mice the synthetic drug was almost equally effective in preventing death after inoculation with about 40 lethal doses of *R. tsutsugamushi*.

In two cases of scrub typhus the synthetic drug produced the same dramatic improvement in the patients' condition as had been observed in other cases treated by the fermentation product.

BENIXSON, J. & ANGSTADT, L. Some Observations on the Effect of Cytochrome C in Rickettsial Infections. *Tex. Reports on Biol. & Med.* 1948, v 6 No 4 484-92 [14 refs.]

1. The apparent lengthening of the incubation period of Rocky Mountain spotted fever in guinea pigs following intraperitoneal infections of cytochrome C of varying concentrations as indicated has been postulated as being a nonspecific physiologic effect or a protein effect or both.

2. Cytochrome C therapy begun on the day of fever in typhus and Rocky Mountain spotted fever in relatively large doses for two consecutive days did not alter the course of the fever.

HUBNER, R. J. JELLINEK, W. L. & DECK, M. D. Q Fever—a Review of Current Knowledge. 4. *Intern. Med.* 1949 Mar 30 v 3 493-509 93 ref.]

NACK, E. G. & WEYER, F. Laboratoriumsinfektionen bei Q Fieber (Laboratory Infection with Q Fever. *Deut. med. Woch.* 1949 Feb 18 v 74 No 7 193-702, 2 figs. 1 ref.]

In the course of the investigation previously described this fall of 1948 v 48-541 a laboratory outbreak of Q fever occurred at the Hamburg Tropical Diseases Institut. During a period of three months beginning November 21 1947 seven confirmed and four probable cases occurred and in a footnote mention is made of two further confirmed cases.

The outbreak, which is described at length appears to have been entirely the laboratory outbreak already reported from the U.S.A. and Austria. *Rickettsia* were isolated and detected microscopically in sera and animals from animals and arthropods inoculated with the blood of four patients.

YELLOW FEVER

STEFANOPOULO, G J & DUVOLON, S Réactions observées au cours de la vaccination contre la fièvre jaune par virus atténué de culture (souche 17 D) A propos de 20 000 vaccinations pratiquées par ce procédé à l'Institut Pasteur de Paris (1936-46) [Reactions during Yellow Fever Vaccination with Attenuated 17 D Virus in 20,000 such Vaccinations in the Pasteur Institute Paris in 1936-46] *Bull et Mém Soc Méd Hôpît de Paris* 1947, Nos 32/33, 990-1000 [26 refs]

In this review of 10 years' experience of inoculation with the yellow fever vaccine the authors draw particular attention to the lack of harmful reactions in the recipients of the chick embryo vaccine containing the attenuated strain 17D of yellow fever virus. The neurotropic mouse brain vaccine has produced some severe reactions affecting the nervous system particularly in some cases, but they observed no bad reaction in 2,470 infants aged 15 days to 10 years who received the 17D vaccine. The neurotropic mouse brain vaccine has also been known to cause severe reactions in persons past middle age but the authors have seen no severe reactions in 1,500 people aged 45 to 88 who received the 17D vaccine.

The authors have tended to refrain from giving other injections in the week preceding and week following the yellow fever vaccine inoculation.

They draw particular attention to the necessity to ensure beforehand that those to be injected are not sensitive to egg protein. *F O MacCallum*

DENGUE AND ALLIED FEVERS

SABIN, A B & YOUNG, I A Complement Fixation Test for Dengue *Proc Soc Exper Biol & Med* 1948, Dec, v 69, No 3, 478-80

The antigen used was extracted with benzene from the brains of 3-14-day-old mice inoculated intracerebrally with a Hawaii strain of dengue virus which had been greatly exalted in virulence by repeated passages through mice of three to four days old. With this antigen complement-fixation titres of 1-64 to 1-256 were observed within two to six weeks of inoculation, in human volunteers, rhesus monkeys, and chimpanzees, infected with the homologous strain of human virus. The reaction persisted for many months, titres ranging from 1-4 to 1-16 were observed up to 52 months after infection. Human volunteers inoculated with immunologically distinct strains of human virus gave titres of 1-16 or less, and within six months the reactions became negative. These volunteers developed little or no neutralizing antibody for the Hawaii virus, neither did rhesus monkeys inoculated with the same strains though they gave complement-fixation titres as high as 1-512, but even at the lowest titres the reactions were incomplete (2-3 plus) and they became negative 6-10 weeks after inoculation. On the other hand a rhesus monkey inoculated with the Hawaii strain developed neutralizing antibodies at high titres though the complement-fixing titre was only 1-16 against the homologous antigen.

Human volunteers inoculated with a live vaccine made from mouse-adapted Hawaii virus became immune to unmodified human virus though the complement-fixation test remained negative.

Sera of persons who had been attacked by dengue two years previously in Hawaii, Japan, Singapore, Java, and New Guinea, contained high-titre neutralizing antibodies against the Hawaii virus and also gave complement-fixation

The louse suspensions were not infective to mice by intranasal or other routes. Transfer of the rickettiae to headlice and tick (*Ornithodoros* spp.) were made by methods already described by the author [above].

Dried faeces of infected lice were still infective by intrarectal inoculation for body lice after storage for 2½ years.

John H. D. Meyer

BARTONELLOSIS

SILVA PYRALTA, P. Un caso de neuro-bartonelosis. Tratado por penicilina. A Case of *Bartonella* Infection with Nervous Symptoms. *Rev. Med. Peruana* 1948, Oct. 1, 21 No 238 641-50

The patient a girl of 15 years was taken ill with a general feeling of malaise and intense fronto-occipital headache accompanied by tinnitus. Her temperature on the third day was 38°C. She also complained of acute epigastric pain with nausea which, however soon left her to return again 3 weeks later and again disappear. On or about the 14th day of disease she had wandering pains in the bones and became progressively weaker so that after 4 days she could not leave her bed—the left leg felt cold and numb vision became blurred, people appeared like shadows and she was very breathless. She lost a considerable amount of weight.

Clinically she was thin and pale, respiration 35 per minute, pulse 140. Muscles tender especially those of the neck, lips tremulous. Deep reflexes were exaggerated (they are usually said to be diminished or even lost in the severe anaemia of *Carrión's disease*). There was no change in sensation. A functional presystolic bruit was heard over the aorta, the pulmonary and the tricuspid areas but not propagated, lungs normal. There was slight enlargement of the cervical, inguinal and femoral glands which however were painless and mobile. Blood examination: red cell 850,000 (next day 895,000) leucocytes 10,950 (11,350 next day) per cmm and 60 per cent. 11 the red cells showed *Bartonella* there were anisocytosis and poikilocytosis and 16 per cent. were normoblasts.

Treatment with penicillin was started on the first day that the patient came under the author's observation the 24th day of disease. She was given 30,000 units every three hours intramuscularly. Four days later when 600,000 units had been given the red cells had increased to 1,390,000 and the white reduced to 7,950 and *Bartonella* were no longer seen in the blood. Improvement was uninterrupted and 10½ weeks after the treatment was started blood examination showed red corpuscles 4,400,000 leucocytes 7,950 per cmm. The reflexes became normal, vision improved in a fortnight and was normal in 3 weeks, and helped by passive movement the muscular weakness cleared up. During the penicillin 5 million unit in all the patient received liver extract, vitamin C 500 mgm and vitamin A 100 mgm daily.

H. H. Reid & A.

Hoplopsyllus anomalus, these were believed to have transmitted infection from ground squirrels to the rats and also from rat to rat, because the other fleas found on the rats were the relatively poor vector, the mouse flea (*Leptopsylla segnis*) and a few fleas of the species *Nosopsyllus fasciatus*

No rat fleas were found on any of the 53 squirrels taken in the vicinity of the ranch so that transmission from rat to squirrel was regarded as having been unlikely to occur

In view of the findings the authors stress the necessity for effective rat control in places where plague occurs among wild rodents

The paper contains a great deal of documented information regarding the rodents and fleas known or suspected as agents in the transmission of epizootic plague in the U S A

Bacillary type cases with negative culture responding to sulphaguanidine	698
Admitted late without laboratory investigation and responding to sulphaguanidine	115
TOTAL	1 430

In the search for carriers the following procedure was adopted. Each patient was detained in hospital after the cessation of sulphaguanidine therapy, the next stool was then cultured and the patient discharged without waiting for the result. Those found positive were readmitted and given a course of 100 gm of the drug. All were then found to be free of infection.

The table of carriers is as follows —

Organism	Carriers	Total Recorded	Percentage of Total
<i>Sh flexneri</i>	21	358	5.9
„ <i>sonnei</i>	8	99	8.1
„ <i>schmitzi</i>	2	49	4.1
„ <i>shigae</i>	1	19	5.3
„ <i>boyd</i>	3	24	12.5
TOTALS	35	549	—

Amoebic dysentery was treated with sulphaguanidine (4 gm every four hours to a total of 20 gm), followed by 10 days of emetine (1 grain daily) and five days of quinoxyl (0.25 gm three times daily by mouth and a retention enema of 5 gm in 200 cc of saline each evening). Seven patients relapsed within a year.

Bacillary dysentery was treated with sulphaguanidine (4 gm every four hours night and day) until patients were afebrile and symptomless. The dosage for the different groups is analysed in a table and the average requirement for each group is given.

The only significant complication was acute hepatitis, which occurred in 10 cases. There were no deaths in the series.

P. Manson-Bahr

The majority of the strains possessed 3 or 4 of the antigens.

As the A antigen was present in all the agglutinable strains examined and absent from all the non-agglutinable strains the author concludes that the demonstration of its presence regardless of the titre of agglutination, is necessary and sufficient for the diagnosis of *V. cholerae* the El Tor vibrios, which do not show any difference in antigenic structure from the cholera vibrios being differentiated by the usual haemolytic test. The demonstration of the B and C antigens serve to distinguish the Ogawa, Inaba and Nikojima types, but only if present along with the A antigen as these fractions have been found in the "non-agglutinable" vibrios. It is considered that the use of monospecific sera prepared for the B and C factors may lead to error in the diagnosis of the three types on account of the presence of antibodies against subsidiary fractions unless the complete antigenic formulae of the strain used in manufacture have been ascertained.

In view of the presence of the B and C antigens in non-cholera vibrios it is concluded that these are non-specific. No importance is attributed to the D to M antigen from the point of view of diagnosis although these may be of interest in relation to the geographical distribution of strains.

The selection of strains for cholera vaccine is discussed in the light of the findings. It is suggested that stock vaccine should contain all 19 antigenic fractions and that the vaccine should be modified during the course of an epidemic in accordance with the predominance of the several factors found in the strains isolated. In the absence of detailed information on the antigenic structure the alternative empirical measure might be the inclusion of a number of strains in the vaccine. At the Pasteur Institute of Paris six strains possessing between them most of the fractions are used for manufacture.

In his examination of the Egyptian epidemic strains the author found the predominant antigens to be A, C, D, E and L and he considers that the optimum vaccine under the circumstances would have been one that contained these 5 factors. As no Ogawa strains were isolated the point is raised whether the use of a vaccine containing equal proportion of Ogawa and Inaba strain may not have entailed the risk of the production of inappropriate antibodies and an insufficient level of those which would be useful.

J. Taylor

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

SYMINGTON S. Dysentery in South Persia. *Brit. Med. J.* 1919 Apr 16 602-3.

This survey concerns a permanent and static civilian population and therefore has a certain value greater than surveys of the same diseases under war conditions. The statistics are based upon the initial laboratory examination of stool from all cases regarded as dysentery in the Anglo-Iranian oil company's 20,000 male artisan employees on Abadan Island.

The rarity of amoebiasis is specially commented upon. Proved amoebic dysentery accounted for only 1.8 per cent, whereas proved bacillary infections accounted for 37.3 per cent, and a further 36.4 per cent. were of bacillary type but unproved. Diagnostic findings are classified below—

coli is being maintained in the presence of a bacterial contaminant *Trichomonas vaginalis* and *T. hominis* grow with great ease and can be isolated from old specimens with no visible organisms. *Balantidium coli* also grows easily, but streptomycin inhibits the establishment of the initial cultures. Attempts to cultivate *Endolimax nana* and *Giardia intestinalis* were unsuccessful.

MILLER, M J & FIRLOTTE, W R. Studies on Amoebiasis in Canada. Part II. A Method for obtaining Viable Cysts of *Entamoeba histolytica* free from Bacteria. *Canadian J Res Sect E Med Sci* 1948, Dec, v 26, No 6, 299-302, 3 figs (2 on pl)

Inoculation of a modified Boeck & Drbohlav medium with sterile cysts of *Entamoeba histolytica* was performed in the following manner. Infected stools were obtained from inhabitants of a boys' orphanage. Cysts were concentrated by a zinc sulphate flotation method and were washed and suspended in sterile Ringer's solution to which penicillin (500 units per cc) and streptomycin (1000 units per cc) had been added. A resistant streptococcus was eventually eliminated by picking up the cysts with a micro-pipette and resuspending them in Ringer's solution plus antibiotics, the process being repeated five times. Details of a modified micro-pipette apparatus are given. The entire procedure takes about 8 hours to complete.

The method was devised in order to test the growth requirements of the amoebae. Various strains of bacteria were added to the culture tubes in order to discover those which best sustain growth. It is stated that the details of these experiments will be communicated later [for Part I of this series, see this *Bulletin*, 1948, v 45, 1083].

LYON, E. Chronic Hepatitis in connection with Amoebiasis. *Acta Med Orientalia* 1948, Sept-Oct, v 7, Nos 9/10, 175-81 [18 refs]

Four cases of chronic amoebic hepatitis are described. The author considers that two aetiological factors must be taken into consideration—an organotropic factor owing to the affinity existing between the amoebiasis and the liver—and an allergic one which is mainly brought about by constitutional features.

The main symptoms are paroxysmal pain and swelling of the liver. The functional liver damage gradually subsides.

A prompt response to emetine and yatren treatment was not noted. No efforts should be spared to protect the liver tissue—a low fat, but high carbohydrate and protein diet is required. Owing to the patients' lack of appetite, casein hydrolysates had to be used in order to avoid protein exhaustion. In particularly violent attacks of pain, sympathetic anaesthesia (paravertebral block) may be indicated, but antistim orally has been given with good results.

P Manson-Bahr

TURNER, E. A Case of Cerebral Amoebic Abscess treated by Modern Chemotherapy. *J Neurol Neurosurgery & Psychiatry* 1948, Nov, v 11 (ns), No 4, 291-3.

STEIN and KAZAN in 1942 (*J Neuropath Exper Neurol* 1942, v 1, 32) described the sixtieth case of cerebral amoebic abscess in the literature—in only fifteen of the sixty were amoebae actually seen in the contents of the abscesses.

It is a matter for speculation whether cerebral amoebic abscess may not be curable with modern chemotherapy.

AMASTOPOULOS B. A Preliminary Note on Routine Culture Methods for *Endamoeba histolytica*. *Puerto Rico J. Pub. Health & T. of Med.* 1947 Mar v 24 No 3 240-4. [Spanish version 243-5]

In Porto Rico the author cultured 100 faecal samples } to 24 hours old, for *Endamoeba histolytica*. The Boeck Drbochlay medium was used [this *Bulletin* 1925 v 22 727] with Locke solution inactivated human serum and rice powder. omission of the serum did not appear to affect the results.

Subculture was made every 48 hours on 2 to 4 occasions each (in one case subculture was continued for 5 months).

All but one of the specimens which were positive microscopically for *E. histolytica* were positive in culture. 10 which were negative microscopically were positive in culture. Excystation usually occurred in the first culture though in a few cases amoebae grew only after the first or second transplant.

A table shows the percentage positive findings of intestinal protozoa in the stool, by direct and by culture examination. In the case of *E. histolytica* 7 per cent. were positive microscopically and 18 per cent. on cultivation.

Another table shows the incidence of protozoa among various groups of Porto Ricans based on single stool examinations as found by different workers [see this *Bulletin* 1928 v 25 244 1934 v 31 281 1935 v 32 344 1946 v 43 1143]. The present author's finding of 17 per cent. in the 100 samples studied "indicates a slightly higher incidence of the parasite than has been reported to date from Puerto Rico." [But this does not take account of LOTIC and FELSENFELD's finding of 17.33 per cent. of *E. histolytica* among patients in Porto Rico by means of direct smear and flotation. see this *Bulletin* 1948 v 45 1005.]

The author considers that this cultural method may be used for routine diagnosis of intestinal protozoa especially where undifferentiated pre-cystic stages or a few doubtful cysts are found by other methods.

H. J. O'D. Burke-Gaffney

SHAFFER J. G. RYDEN F. W. & FRYE W. W. Studies on the Growth Requirements of *Endamoeba histolytica*. IV. Further Observations on the Cultivation of *E. histolytica* and other Intestinal Protozoa in a Clear Medium without Demonstrable Bacterial Multiplication. Some Modifications and Simplifications of the Medium. *Amer. J. Hyg.* 1949 Mar v 49 No 2, 127-33.

The medium previously described by these authors this *Bulletin* 1948, v 45 786 787 1001 has been simplified by the omission of the filtrate of the bacterial complex and now consists of the following —

- 2 cc. normal saline
- 0.5 cc. normal horse serum
- 500 Oxford units of penicillin G sodium,
- 2.5 cc. pre-conditioned thioglycollate medium.

The last ingredient is the supernatant fluid from a centrifuged 24 hour culture of the special streptobacillus. It contains trypticase dextrose salt methylene blue agar sodium thioglycollate and between 10 000 and 100 000 streptobacilli per cc. It is highly labile and must be used within a few minutes of preparation. Anaerobic conditions are essential for successful cultures. The first inoculation must be into media containing larger quantities of antibiotics (1 000 Oxford units of penicillin and 1 500 units of streptomycin per cc.) The technique is unsuitable for routine diagnostic procedures but its employment will help in determining the food requirements of intestinal protozoa.

Six strains of *E. histolytica* have been isolated and maintained in the new medium, including one strain derived from cyst alone. A culture of *Entamoeba*

of cases The clinical course of the disease in cats with pure bacterial infections and those which were also infected with amoebae ran a parallel course The majority of animals died after a week and a few after two days They wasted away with fever and passed diarrhoeal blood-stained stools

Histopathological studies revealed extensive mucosal necrosis in the bacterial infections, with oedema and hyperaemia of the submucosa The bowel lumen was filled with detritus and mucus and the inflammatory process extended into the small bowel In some cases the lungs, liver and spleen were affected

In the majority in which combined infection with amoebae had been established the cellular picture was identical, save that in the most extensive necrotic areas amoebae could be demonstrated It is not suggested that these cases in which the amoebae lived in the necrotic detritus could be regarded as genuine cases of amoebic dysentery In genuine intestinal amoebiasis the amoebae burrow into functionally healthy tissues in contrast to the former condition where these organisms are merely existing in the form of exaggerated intestinal parasitism [as opposed to tissue parasitism] Quite exceptionally the combined amoebic infection loses its secondary character In their normal course the amoebae by fermentative cytotoxicity invade the muscularis mucosae The less pronounced the bacterial infection the more typical the amoebic lesions become It was established that synergic infection was primarily brought about by haemolytic streptococci and that they were responsible for the bacterial spoiling, but later they were superseded by a pathogenic variety of *Bact coli* An associated trichomonas infection appeared to play no part The bearing of these observations on the clinical picture in man should be critically assessed

P Manson-Bahr

COUTELEN, F, BIGUET, J & COCHET, G Déterminisme de la phagocytose expérimentale de divers amidons par *Entamoeba invadens* [Experimental Study of Phagocytosis of Different Starches by *Entamoeba invadens*] *Bull Soc Path Exot* 1948, v 41, Nos 11/12, 652-6 [15 refs]

Cultures of *Entamoeba histolytica* are known to be most prolific when the medium contains rice starch, other forms of starch are much less suitable The phagocytosis of different starches by the reptilian amoeba, *E invadens*, was compared, and rice, arum, oats, maize, arrowroot, barley, pea, wheat, rye and potato were studied The size of the granules of these starches was measured Unlike the human amoeba, the snake amoeba actively ingested all the materials, even the potato starch which was present in grains about 30-60 μ in diameter These were the largest of all those tested and were least utilizable It was remarkable that granules 32 μ in diameter could be ingested by organisms measuring themselves only 36 μ Nevertheless, a preference was shown for the smaller types e.g. rice starch at 4-6 μ , this also was found to possess the additional advantages of being regular in form and not liable to agglomeration Arum starch also shows these properties and is equally effective in cultures of the organism

The starch is stored as glycogen in the endoplasm of the amoeba, where its presence can easily be demonstrated by the use of Lugol's iodine solution

In this paper the evidence in favour of the amoebic origin of the multiple cerebral abscesses is open to criticism. The patient a soldier had served only nine weeks in India before his admission to a military hospital. He presented the classical signs of cerebral abscess in the temporal lobe. In the pus abstracted through a burr hole by left temporal incision chains of streptococci were seen in a direct smear. Later the brain was tapped again and a second intracerebral abscess was entered behind the first. The pus was at first thin and watery and on direct examination numerous vegetative amoebae actively mobile were seen in a slide. Cultures later produced non haemolytic penicillin resistant streptococcus. At necropsy the brain showed widespread meningo-encephalitis with the left hemisphere riddled with abscesses. In sections groups of streptococci were seen but no amoebae.

The patient was treated with sulphonamides, penicillin, streptomycin and emetine but the last-named was only begun 3 months after the illness started. The illness lasted for 4½ months and ended fatally. *P. Manson-Faulk*

ZUIDERMA, P. J. Over emetine-intoxicatie. [Emetine Intoxication.] *Ned Vaezkdlaal*, Batavia, 1949 Feb. 1 v 2, No 2, 33-7 1 chart.

The English summary appended to the paper is as follows —

In an Indonesian patient, 6½ years old, severe myocardial damage occurred after 9 subcutaneous injections of 60 mg emetine each corresponding with 7 mg emetine per h.G. body weight. The pulse rate suddenly rose to 128. The electrocardiogram revealed a lowered ST segment in Lead 1 and 2, a negative T in Lead 2 and 3 and a flat T in Lead 1. No other signs of intoxication were noted.

Notwithstanding absolute rest in bed it took 3 weeks for the pulse rate to drop gradually to its original height. Another electrocardiogram, taken 4 weeks after the first, showed that the abnormalities had disappeared for a great deal.

"Probably in this patient a high individual susceptibility existed for the drug. This is also suggested by the history of the patient since in 1918 after 7 injections of emetine (dosage not known) a complete paralysis of the extremities occurred, for which a stay of several weeks in hospital became necessary."

At the present time cardiac damage was the only clinical evidence of intoxication. It is suspected that organic heart disease existed already before emetine treatment was initiated."

WESTPHAL, A & MARSHALL F. Amöbenruhr bei Katzen auf bakterieneller Grundlage. [Amoebic Dysentery in Cats in relation to Associated Bacterial Infection.] Reprinted from *I volker Arch f Path Anal u Physiol* 1941 v 308 No 1 22-44 9 figs.

The connexion between the establishment of amoebic dysentery and previous bacterial injury has been established by WESTPHAL in man (ibid. *Bulletin* 1950 v 36 [288]) and DESCHENS (ibid. 31) and others in cat and the work suggests a combined action. The present work has been planned on a different basis in that the bacteria used had been associated with a strain of *F. histolytica* which had been rendered virulent for cat. By comparison of infection with bacteria alone with those caused by the combined amoebic action it was hoped to decide by means of rectal injections, what particular rôle the amoebae played. From experiments conducted on three lines it was decided that the symbiotic bacteria alone sufficed to bring about fatal dysentery in the majority

once exceeded that of Fijians and the totals during that period have been 63 Fijian and 58 Indians, despite the great preponderance of the latter patients

The epidemiological importance of these findings is discussed as the Indians live more independent and less supervised lives, it is much more likely that undetected cases would occur among them

Of the 52 admissions from the Gilbert Islands, 23 were fairly advanced and 16 were very advanced lepromatous cases over 80 per cent were infective War conditions and enemy occupation would have caused deterioration in the position The finding of 7 moderately advanced cases out of 9 Samoan admissions is more disturbing, and the author indicates the urgent need for special training of medical assistants in these islands who would be allocated to a travelling diagnostic survey, as has been done successfully in the Cook Islands where admissions are now among the earliest cases in Makogai

Tables show in detail the distribution of cases in terms of nationality, types of disease and progress, the incomparably better outlook in early neural cases being obvious

The Medical Superintendent took with him on visits to Samoa, Tonga and Niue Island a 16 mm film dealing with Makogai and it was evident that this was greatly appreciated

There were 8 deaths from tuberculosis, five of the patients being diagnosed during the year The importance of this rapid development of the disease in those under fairly close medical supervision is stressed

At the end of the year, 13 cases of tuberculosis remained these had been confirmed by the tuberculin test, X-ray and sputum examination Four of the patients were Gilbert Islanders, two each Indians and Fijians, and one each from other islands Routine tuberculin tests and X-ray examinations are being made as far as possible, despite shortage of films and drugs In 1947, a total of 266 X-ray examinations were made 79 of these were of bony lesions

An imposing list of items of food and other materials produced at Makogai in the year includes 840,000 lb of vegetables, 99,858 lb of bread and 39,126 lb of beef There were also 5,657 gallons of milk and 4,457 eggs An interesting item is the production of over 9,000 lb of soap

The only major constructive work possible during the year was the erection of a new school building for the boys

[This is an instructive account of an admirable institution it is regrettable that post war difficulties should make delay in improvements and extensions inevitable]

INYES J R. Leprosy in Kenya. *East African Med J* 1949 Feb v 28 No 2, 32-5

This study, carried out in the second half of 1948 followed the lines of the author's leprosy survey in Uganda [this *Bulletin* 1949 v 46, 287]. Detailed statistics are shown in two tables. In all, 53,814 persons were examined in seven main areas including the coast inland and highlands. The incidence of leprosy averaged 10.2 per thousand, the highest being the Vvanja area (31.7) and the lowest the Taita Vot-Sagala area (0.9). The estimated number of cases in Kenya put at 35,000. The Juhos tribe were the most heavily affected and the Wateta, Kipsigis and Nandi the least. The author suggests that the course of spread is probably from West to East and not from the coast. The type of leprosy in Kenya is described as "something in between moderate and severe" about 20 per cent of cases are of the infectious lepromatous type and because of living conditions of the people a low increase of the disease appears to be inevitable at present. The general observations are largely similar to those in the case of Uganda: overcrowding and high humidity especially the first are influential factors in stimulating a high incidence of the disease. Movements of the people and especially absorption of members of highly affected tribes into employment may enhance the spread.

Facilities for treatment and control are inadequate: only 60 to 60 cases are under effective modern treatment and some 200 others are in two leprosy camps. There is obvious scope for an active campaign with modern facilities and propaganda.

AUSTIN C J. Central Leprosy Hospital, Makogai (Annual Report 1947). *Fiji Legislative Council Council Paper No 40* 1948 Appendix B 34-40 1 diagram.

Dr Austin's report on the Central Leprosy Hospital Makogai gives an informative account of the position during 1947 supported by 8 useful statistical tables and a diagram.

At the end of 1947 there were 703 patients in the hospital, an increase of 90 during the year of these only 19 were from Fiji itself and the remaining 73 came from neighbouring island principally the Gilbert Islands which contributed 45 patients to this increase.

New admissions amounted to 146 of which 64 were from Fiji and 82 from other South Pacific territories. It is noteworthy that 46 of the 146 admissions were Indians and only 14 were Fijians. Furthermore the number of Indian patients increased by 27 during the year and the Fijians decreased by 5. The ratio of Indian to Fijian men treated at Makogai is indeed steadily increasing and is now well over 2:1 and 19 of the 46 Indian admissions are in fairly advanced and infective lepromatous stages compared with only 3 of the 14 Fijian admissions.

In fact some 70 per cent of the Indian patients are in the lepromatous stage which contrasts with findings in India where the neural type largely preponderates. This situation in Makogai is further reflected in the fact that of 23 deaths 9 occurred in Indians and that of 30 discharges only 10 were Indians. During the past 4 years the annual discharge of Indians has only

once exceeded that of Fijians and the totals during that period have been 63 Fijian and 58 Indians, despite the great preponderance of the latter patients

The epidemiological importance of these findings is discussed as the Indians live more independent and less supervised lives, it is much more likely that undetected cases would occur among them

Of the 52 admissions from the Gilbert Islands, 23 were fairly advanced and 16 were very advanced lepromatous cases over 80 per cent were infective War conditions and enemy occupation would have caused deterioration in the position The finding of 7 moderately advanced cases out of 9 Samoan admissions is more disturbing, and the author indicates the urgent need for special training of medical assistants in these islands who would be allocated to a travelling diagnostic survey, as has been done successfully in the Cook Islands where admissions are now among the earliest cases in Makogai

Tables show in detail the distribution of cases in terms of nationality, types of disease and progress, the incomparably better outlook in early neural cases being obvious

REYES, E, BARRIENTOS, E, RODRIGUEZ, J J, CARRANZA AMAYA, A & PERALTA, R Severe Reaction resembling Therapeutic Shock in Lepers following Administration of "Diasone" *Arch Dermat & Syph* 1949, Jan, v 59, No 1, 118-19

Two patients in San Salvador, aged 39 and 12 years, were treated for lepromatous leprosy, confirmed bacteriologically After some months of treatment in 1946 with chaulmoogra oil, later replaced by promin, the nodular eruptions disappeared almost entirely

In May 1947, diasone was introduced as a routine treatment in the authors' department and each patient was given "a daily dose of 0.3 gm given three times a day by mouth" After 8 weeks of such treatment, the two patients in

question complained that their former eruptions were again breaking out. Examination showed that nodules were spread over exactly the same area which they had originally covered. This phase was accompanied by migraine, epiphora, nausea and fever. Dione therapy was suspended and the phenomena disappeared gradually within 3 days. At the time of the appearance of the reaction, the patients had received 15 g. and 10 g. of dione respectively.

It is added that two weeks later dione was given again to the first patient and the eruption reappeared within 4 days with greater intensity and took a longer time to disappear. Hence in such cases dione should be completely discontinued. The authors note that although such reactions as vomiting, diarrhoea and allergic dermatitis have been recorded with the use of dione the present reaction appears not to have been described. They liken it to the Herxheimer reaction.

CAPURRO E. T & GUILLOT C. F. Vitaminoterapia D₂ a alta dosis en el tratamiento de la reacción leprosa tuberculoide. [Treatment of the Leprous Reaction in Tuberculoide Leprosy with Vitamin D₂ in large Doses.] *Rev. Argentina Dermatología* 1946 July-Dec. v. 12, No. 34 287-91

Charpy has used pure vitamin D (Sterogyl 15) in alcoholic solution for leprosy patients in doses of 15 mgm., three during the first week, two weekly for the next three weeks and thereafter once a week till a year. Treatment had been completed. The results were reported as striking (*brusques*) the inflammation, oedema and erythema disappeared in a few days and the nodules though more resistant, became smaller and in time they also disappeared. Charpy explained its action thus: "Vitamin D₂ in large doses properly paired with a diet not too acid and not too alkaline and with a proper amount of calcium creates in the tissues a state of permanent acidity. Apparently this state induces leprosy sterilization and cur of tuberculous lesions. Mycobacterium and Mycobacteria being closely allied the authors decided to try the same treatment in the acute reactional states of tuberculoide leprosy."

Five patients started the treatment in September 1946. In four the lesion began to improve within 7-10 days and they were cured (in the authors' word there was 100 per cent. improvement) in 45 days and the vitamin treatment was stopped in January 1947 that is after 4 months. One gave up the treatment because of intercurrent cardiac trouble.

Later a fresh group of 10 patients came under observation. Eight kept up the treatment which was modified somewhat from the original 600,000 unit were given three weekly for 3 weeks. Detail of one patient: a woman 43 years of age, with the remark that the others responded similarly. This patient had already been treated with chaulmoogra, the oil and the ethyl esters and with promin and other drugs. Improvement began after 7 days and continued without setback. The nasal obstruction cleared in 3-4 weeks. The maculae lost their colour and desquamation was copious. There appears to be some confusion about the dosage in unit. In one place it is stated that the patient took three ampoules in the week (total 180,000 unit). If the dose was an ampoule of 600,000 unit this total should be 1,800,000. Later it is said, another three ampoules were taken or altogether 6 ampoules of 300,000 unit (1,800,000). Three more in the third week that is a total of nine ampoules or 5,400,000 which is correct. Altogether in the first month there were given eleven ampoules of 600,000 unit (should be 6,600,000). During the second month one ampoule a week. Total six ampoules or 3,600,000 unit (this should be 2,400,000 unit).

HELMINTHIASIS

ROBERTS, J I A Protozoological and Helminthological Survey of Three Races
in Nairobi, Kenya *J Trop Med & Hyg* 1949, Mar, v 52, No 3, 49-59,
2 charts

This is a record of seven years' routine examinations of stools of people living in Nairobi, Kenya. The specimens came from in- and out-patients (European, Asian and African) and were examined direct and after centrifugation, in saline and iodine-stained preparations. 33,166 European specimens, 40,503 African and 5,409 Asian were examined. More than half of the European and three-quarters of the African specimens showed the presence of parasites. Helminthic infections were light and the cases were regarded more as carriers than as victims. There were few symptoms and little or no anaemia. Nevertheless, the author suggests that the mild toxæmia arising from the infections is of major importance in causing an almost life-long damage to the power of development, leading to general mental and physical apathy. The backwardness of tropical populations is said to be associated with this toxic absorption [Unfortunately no proof of toxæmia or of its direct relation to these conditions of apathy is presented. The fact that the mental and physical powers of newly-recruited African technicians improve after anthelmintic treatment, may easily be ascribed to changes in environment, better food, etc.]

Schistosomiasis is ranked high as a cause of ill-health (1.6 per cent of all specimens contained ova), *S. mansoni* infections are found from the coast to 8,000 feet above sea-level. No collections of water in inhabited areas of Kenya can be regarded as free from the possibility of infection. The chief molluscan host is *Biomphalaria pfeifferi*, another is *Bulinus tropicus*. Other important helminths were *Taenia saginata* (9.0 per cent), *Ascaris* (4.3 per cent), and *Necator americanus* (5.3 per cent).

Entamoeba histolytica is essentially found in town-dwellers, it is rare in rural areas. The incidence of the infection is highest in the hot dry season. It is more commonly associated with mild symptoms of abdominal discomfort than with dysentery. In the latter case, the vegetative forms are said to be always larger than in the former. For a year, cases were classified according to the presence or absence of ingested red blood cells in the amoebae—there were only two cases with ingested cells and 80 without. *Giardia intestinalis* was the cause of a chronic mucous diarrhoea in both adults and children. Six cases of balantidial dysentery were encountered. A survey of 86 intestines from pigs slaughtered in the Nairobi abattoir showed that 32 per cent were infected with *Balantidium*. In the main table, 79 cases of *Isospora hominis* are recorded, without comment. [In view of the comparative rarity of this infection, as indicated in the literature, it would have been an advantage if some amplification of this interesting finding had been given in the text.]

OSORIO M. Teresa. Sobre una modificación a la técnica de cuenta de heces de Stoll. [A Modification of Stoll's Method for counting Helminthic Ova. *Rev Inst Salubridad y Epidemiol T op Mexico*. 1948 Sept 10 No 7 245-52.]

For his experiments the author used puppies 2-6 months old and infected them with 1 *Cylostoma can num*. His modification of the Stoll method is slight but he claims that it is quicker easier in not needing any special chemicals can be carried out by any practitioner and is practically as accurate. He places 1 gm. of faecal matter in an Erlenmeyer flask, adds water to the 30 cc mark and 10 glass bead inserts a rubber stopper and shakes well to obtain a homogeneous suspension. He extracts 0.1 cc. with a capillary pipette places it on a slide with a coverglass 20x40 mm. and counts all the eggs in the preparation. He repeats this with a second sample and multiplies the total result by 100 to obtain the number of ova in 1 gm. of faeces. The difference from the classical Stoll method consists in adding water instead of decinormal soda and diluting 10 instead of 15. He made 41 counting by the methods of Stoll Lane Caldwell and this modified Stoll and shows in tables that the results obtained by his modification are really comparable with and closely similar to those with the original Stoll and on the whole better than with the Lane or Caldwell methods.

BOYILLA NAIR, A & GÓMEZ VARGAS M. "Aer y faust, faust simplificado. Dos nuevos métodos para investigar parásitos intestinales. [The AEX Method and Faust's Method (Simplified) for detecting Intestinal Parasites.] *Repertori Med y Cirugía*. Bogotá. 1948 v 4 No 1 49-68 48 refs.]

These two procedures are detailed and the authors then compare the results obtained by these and the standard method of Will-Mallory and the Stoll techniques and direct examination.

By the AEX method of Loughton & Stoll, 50 cc. of tap water are placed in a Stoll flask and 4 cc. of faeces emulsion in water added. The whole is vigorously shaken with glass beads to obtain a homogeneous product. 1.5 cc. of this placed in a 15 cc. centrifuge tube and to this are added 3.5 cc. of 20 per cent HCl after stopping with a rubber plug the mixture is shaken for one minute then put aside for two minutes. Next 3 cc. of a mixture of ether and xylol in equal part are added and the whole is again shaken for one minute and centrifuged at 1,000-2,000 r.p.m. for two minutes. The material collected on the walls of the tube is carefully removed by a thin piece of wood, the supernatant is poured off and one drop of decinormal NaOH added to the deposit some of this deposit is removed with a capillary pipette and examined.

The original Faust method, say the authors is inconvenient in needing several manipulations and is time-wasting. The first-named author Dr B. M. Naair has modified it thus. He mixes about 1 gm. of faeces in 10-12 cc. of zinc sulphate solution sp. gr. 1.100 in 15 cc. centrifuge tube and centrifuges for 5 minutes at 1,500-2,000 r.p.m. With a capillary pipette or a loop material is taken from the surface placed on a slide and examined.

The authors give the results of 100 samples examined at their laboratory by each of the 2 methods and conclude:

1. The AEX method was the best for finding ova of hookworm, *Trichuris* unfertilized faecis and larvae of *Strongyloides stercoralis*. By it also cysts are found but mostly unchanged to prevent difficulties in identification.

2. The Simplest Faust method is better service for helminthic ova but is the method of choice for protozoal cysts.

3 The *Willis-Mallory method* was good for concentrating helminth ova, but not so good as AEX because unfertilized *Ascaris* does not show up and neither larvae nor cysts were found by it

4 *Stoll's original method* was useful for helminth ova and larvae, but less so than AEX or the Willis-Mallory

5 *Direct method* was the only one to show trophozoites of *E. histolytica* in acute amoebiasis and in only 50-70 per cent were helminthic ova found, in 43 per cent *E. histolytica* and in 83 per cent *Giardia intestinalis* were found

"In none of our preparations did we meet with ova of *Enterobius vermicularis* which confirms the rarity of this in the faeces [here] and the need for using Hall's Cellophane method or some modification of it"

NEVES, A de O A esquistosomose no Estado do Espírito Santo
[Schistosomiasis in the State of Espírito Santo] *Anais Depart Estadual Saude Espírito Santo* 1948, 37-102, 5 maps & 1 chart

After remarks upon the geographical situation, the climate, the hydrographic and other general details of this State of Brazil, the author gives the results of examinations carried out in 18 localities of Espírito Santo. In the majority of them only 100 or so examinations were made and in some much less, so that detailed figures will have little interest. Summing up the examinations of 56,206 faecal specimens in the course of 10 years, 1935-1944, 800 were positive (1.4 per cent). This, however, is regarded as misleading if applied too strictly, for in another set of examinations, among 6,159 there were 759 positive, or 12.3 per cent and at Guandu and Santa Joana, the most severely infested zone, an even higher degree was found, 643 among 2,893 (22.2 per cent). The vector is *Australorbis centumetralis*

H Harold Scott

ERFAN, M, ERFAN, H, MOUSA, A M & DEEB, A A Chronic Pulmonary Schistosomiasis a Clinical and Radiological Study *Trans Roy Soc Trop Med & Hyg* 1949, Mar, 42, No 5, 477-85, 6 figs on 4 pls [10 refs]

From 103 parasitically diagnosed cases of urinary and intestinal schistosomiasis at the Fouad I Hospital in Cairo 49 cases of pulmonary schistosomiasis were selected for study. The diagnosis rested on the fact that the patients had a proven gut or bladder infestation, and radiological changes in the lungs which improved after antimony treatment. Forty-four of the patients were males and the rest females, this sex-disproportion is in part due to the reluctance of women to enter hospital, the ages of the patients ranged from 10 years to 55 years (children below 10 are not admitted to this hospital).

The onset of symptoms was insidious, those commonly encountered were dyspnoea on exertion, cough (and in one case slight haemoptysis), general weakness, giddiness and fainting, palpitation, and thoracic and praecordial pain.

In 34 of the 49 patients no physical signs were found in the lungs, in 15 there were some moist sounds at the bases, sputum was examined from only 7 of the patients, and in no case were schistosome ova found in it. The physical signs included slight cyanosis (3 cases), clubbing of the fingers (7 cases), and swelling of the superficial cervical veins with congestive heart failure (2 cases). In 28 of the 49 patients there were signs of pulmonary hypertension and dilatation, in most there was accentuation or splitting of the second heart sound and a harsh systolic murmur in the pulmonary area. Forty-one patients had enlargement of the liver, and 38 enlargement of the spleen, 10 had ascites, and 5 oedema of the legs. No patient had a pyrexia due to the schistosomal

pulmonary involvement the haemoglobin values ranged from 15 per cent. to 104 per cent. but in 6 cases the low figure was ascribed to ankytostomiasis the eosinophil counts ranged from 1 to 40 per cent.

Antimony treatment [the drug used is not specified] of 44 of the patients resulted in improvement in some cases, but it caused fever, urticaria, acute pulmonary congestion and a marked eosinophilia in others one of whom died as a result. The pulmonary reaction to specific treatment may be due to allergy or to focal reactions around the lung lesions. Bronchial asthma and a focal pneumonia possibly verminous are their clinical manifestation.

Erfan and Deeb in an appendix classify the pulmonary lesions into three radiological grades. Grade I in which there are focal arterial changes. Grade II in which there are widespread arterial changes with slight heart changes and Grade III in which there are widespread arterial changes with gross heart changes. They detail the lesions they encountered and give illustrative radiographs.

GELFAND M. Schistosomiasis of the Female Genital Tract. *South African Med J.* 1949 Apr 2, v. 23 No. 14 233-7

The author reviews the literature of schistosomiasis of the female genital tract and refers to the difficulties in interpreting correctly symptoms attributable to infections of that tract. Many parts of the genito-urinary tract may be affected by schistosomiasis concurrently and, particularly in Africans, the prevalence of coincident gonorrhoea or other infections may complicate the issue.

Existing literature does not appear to define clearly how frequently the different parts of the genital tract may be affected. The present study made in Southern Rhodesia, was directed towards determining this point and also the relative frequency with which *S. haematobium* and *S. mansoni* respectively settled in these parts.

Thirty African women between 20 and 35 years were studied consecutively at autopsy. Evidence of schistosomiasis was found in each case in either the urinary or intestinal tract. The various organs or parts were dissected and separated carefully and placed in appropriately labelled containers. Each was digested separately for 1½ hours at 60°C. in 10 per cent. caustic potash solution and the digested portions were examined microscopically for ova.

The results are given for the bladder, rectum, vagina, cervix, uterus, arms and Fallopian tubes. The bladder and rectum contained ova in every case. In one case the bladder contained ova of *S. mansoni* in addition to *S. haematobium*. In ten cases the rectum contained ova of both species, in 18 there were only *haematobium* ova and in 2, *mansoni* ova alone.

The distribution of ova in the genital tract of the 30 cases was as follows:—

Number of cases	Number containing only a few ova
Vagina—23	7
Cervix—28	11
Uterus—23	not stated
Ovaries—1	10
Fallopian tubes—16	4

It will be noted that in the majority of positive cases, ova were present in fair quantities, the minority reporting "a few or only."

In every case *S. haematobium* was found in only one of the 12 having *S. mansoni* in the rectum were ova of this species found in the genital tract, this was in the vagina where *mansoni* ova were found in addition to *haematobium* in a single case. The author draws attention to this frequency of ova in the genital tract in *haematobium* infections and their rarity in *mansoni* infections. "It may be assumed that if a patient has urinary bilharziasis, the probability is that she will have ova of *S. haematobium* in some portion of the genital tract." In no case in this series was a genital tract free from ova and generally more than one part was affected. It is noted that the vagina and cervix were most commonly affected.

The author points out that the exact significance of these findings cannot be assessed but "it seems reasonable to argue that in the majority of cases the damage is minimal and symptoms will not be produced, but where the local deposition is severe, particularly in the Fallopian tubes or ovaries, effects from the fibrosis may ensue, resulting in sequelae, such as sterility or ectopic gestation."

TALAAT, S M & SHOAI B, S The Intensive Treatment of Schistosomiasis with Tartar Emetic J Roy Egyptian Med Ass 1948, Dec, v 31, No 12, 961-3

The authors have continued the work already reported [see this *Bulletin*, 1948, v 45, 719]. They have treated 90 hospital patients having schistosomiasis (17 of them under 15 years of age) with intensive courses of tartar emetic [species of schistosome not stated]. Each adult patient received 2 grains of tartar emetic dissolved in 20 cc of 5 per cent glucose twice daily on two consecutive days. As the first five children did not seem to respond to this course, the remainder were given "three injections instead of two" [later it is stated that "children under 15 years of age must be given an extra injection on the third day to ensure satisfactory results"]. There is some ambiguity in the use of the word "injections" which seems in some of the contexts to mean "daily dosage" the exact amount of tartar emetic given to children is not therefore clearly stated.]

Patients were observed for one month, and in a few cases for two to seven months. At the end of the observation period, 73 patients were rid of their ova, two passed dead ova and 15 passed living ova. One month later 10 of these 15 were given a second course and all (with the exception of one child) became free from ova.

The authors state that their modification of injection technique "did not seem to affect or increase the untoward reactions when individual tolerance was observed."

Since the paper noted above was published the authors have found that renal disease does not contra-indicate this form of therapy, so long as urinary output is good they have also given the course to two patients having a haemoglobin percentage of 25 to 30. There were no complications, but nevertheless the authors consider administration of the drug risky in such cases. A decompensated heart and cyanosis are to be considered contra-indications.

Ten of twelve children under 15 who were given the additional treatment ceased to pass ova.

One of the authors has treated 13 private patients without complications. In these cases, the patient rested for 15 minutes before leaving the clinic and was advised to abstain from manual work for a week.

In the hospital cases, the patients were injected with a S15 or 16 bore needle the patient lay flat during the injection and for 10 minutes afterwards.

SCHUBERT M., GOLDBERG Evelyn & SCHNEIDER, Freda G. Comparison of Several Antimonials in the Treatment of Experimental Schistosomiasis Mansonii in Mice *Amer J Trop Med* 1949 Jan., v 29 No. 1 115-27

The results of screening test with various drugs in mice infected with *Schistosoma mansoni* have already been reported in detail by SCHUBERT [*ibid* Bulletin 1948 v 45 620-621]. Comparable dosage of the different antimonials was taken as that approaching the maximum tolerated. A large-scale attempt has now been made to determine the therapeutic indices of the antimonials used against this infection by direct comparison of the LD₅₀ and CD₅₀ (the dose that cured half the mice). Difficulty was found in assessing accurately the LD₅₀. It was determined on infected mice under the same conditions as those in the treated groups and required consideration of the death rate among infected but untreated controls. The mice were infected by intraperitoneal injection of 150 cercariae and the worms were allowed to mature for a period of 8 weeks. During the following 7 weeks groups of 15 mice were treated daily on 6 successive days with various antimonials by intraperitoneal injection except in the case of butyl antimonyl gallate which was added to the diet. Two weeks later i.e. at the 17th week after infection the mice were autopsied and the number, state and distribution (antimonials cause the worm to migrate from the mesenteric veins to the liver) of the worms were determined. Sodium antimony tartrate and urea stibamine appeared to be without effect but neostibosan and neostam had some effect on the worms at maximal dosage. Their therapeutic indices were below 1. Focadin and trihydroxitol showed activity with indices about 1. Three antimony tri-(thiomercaptides) of the general formula Sb(SR)₃ soluble in peanut oil possessed considerable activity as did butyl antimonyl gallate and their therapeutic indices ranged from 2 to 7. Some interesting experimental data are also given which indicate that there is an increase in death rate of the infected mice with advance of the infection. So far as these results in mice go they indicate that some of the Sb compounds described here are more effective against the infection than those generally used. *J. D. Fulton*

ARIM M. A. & ATYAD N. A Preliminary Report on the Value of Palm-Leaf Traps in the Survey and Treatment of Streams Infested with Snails. *Trop Roy Soc Trop Med. & Hyg* 1948 Nov v 42 No 3 231-48 9 figs. & 1 graph.

The authors describe in detail the experiment they made with palm leaf traps in the control of snail in the streams of Egypt. They wished to know to what extent, and at what level snails are carried by large streams, what proportion will be caught by the traps in the presence or absence of other foodstuff, and what is the distribution of snail in a stream under various conditions of current depth, etc. They have illustrated the paper by attractive line drawings of the palm leaf trap in position.

The traps are made of palm leaves chained together in parallel. Each rung consist of two superimposed palm leaves pointing in opposite directions and about 2 metres in length and the rungs are about 50 cm. apart. Some 10-15 rung chained together form the traps and the lowest are weighted so as to reach the bottom of the stream, or hang down into it. The force of the current bulges the traps sometimes very greatly. Snails seek the palm leaves which present a large surface on which they feed or deposit eggs. For finding snail these traps are better than net or the process of dipping.

The result of several experiment in flowing water showed that most of the Bulinus snails caught were found near the surface of the water or about the middle of the traps and that these snails tended to collect where the water

was fairly shallow and the current moderate. The traps functioned well even in the presence of natural food supplies (weedy vegetation) of the snails. In shallow, slow-flowing canals the snails tended to collect on the slopes of the sides, or on the bottom, but in swifter streams they were usually confined to the slopes, and avoided the more swiftly moving water.

In ponds, palm leaves stuck into the banks and projecting into the water collect snails readily, and if they are renewed each week, will greatly reduce the number of snails within a month. Streams may be treated in the same way, but it is advisable to clear the weeds first, and then to stick the leaves into the banks, below the water surface, about 1 metre apart. In this method they are not chained together as in the traps described above. One man can attend to 3 kilometres of bank, removing and replacing the leaves and collecting the snails from them, every week. This method may be used where closure of the canals, and treatment by copper sulphate, are not possible. Certain streams have been so treated for long periods, with good results. [See also this *Bulletin* 1947, v 44, 97.]
Charles Wilcocks

CAWSTON, F. G. Mechanical Purification of River Water [Correspondence]
Trans Roy Soc Trop Med & Hyg 1949, Mar, v 42, No 5, 507-8

In this note, examples are given to show the reduction of coliform bacteria in water which takes place as a result of pumping to raised tanks, and the author considers that "the chances of contracting schistosomiasis are much reduced when water is pumped through metal piping, especially where it is passed through more than one tank and drawn from the bottom layer rather than the surface which harbours those cercariae which attack man."

Flowing water tends to purify itself by contact with stones and by passing over waterfalls but vegetation and molluscs tend to accumulate below waterfalls and to reinfest the water.
H. J. O'D. Burke-Gaffney

BIAGGI, N. & PIRAZZI, R. The Effect of Chloramine on the Miracidia of *Schistosoma mansoni*. *Puerto Rico J Pub Health & Trop Med* 1949, Mar, v 24, No 3, 246-50 [Spanish version 251-5]

"1 Concentrations of chloramine in water, varying from 0.3 to 0.89 parts per million, had a definite effect on the viability of the miracidia of *S. mansoni*.

"2 Chloramine concentrations of 0.45 parts per million inactivated miracidia in an average time interval of 7.2 to 8 minutes.

"3 Miracidia lost their motility in chloramine concentrations of 0.89 parts per million in the maximal time period of five and a third minutes."

KUO SHAO CHOU, YUI HUAN WEN & CHANG CHIANG E. An Abbreviated Report on Field Survey of Schistosomiasis in Szechwan. *Chinese Med J Chengtu* Edition 1945, Apr, v 63A, No 3, 144-8

In 1943 an autochthonous case of *Schistosoma japonicum* infection was found in Chungchingchow, Szechwan, and in 1944 the authors made a survey of that area, and 4 other places round Chengtu, to find other cases, they give details of the people examined, but they did not find any new cases. They also examined over 1,000 snails (*Katayama*), but with negative results. In the mesenteries of 2 of 30 cattle *S. japonicum* was found, but 6 buffaloes and 1 goat were negative. The cattle were heavily infected with *Ornithobilharzia* species.

S. japonicum infection, therefore, is slight round Chengtu. This may be a reflection of the farming practices, for only in summer is the land submerged

for the cultivation of rice and the molluscan host therefore have only half the year to propagate themselves and to receive and transmit infection.

Charles H. Brooks

BEST, A. E., & WE, D. C. Schistosomiasis on the Chengtu Plain, China. *Med J Chengtu* Edition. 1945 Apr., 1: 631 No 3 139-42.

Until 1939 schistosomiasis had not been reported from the Szechuan province of China thereafter hatching tests were done on stools of suspected cases and in five years 15 cases were collected. In one case the miracidium was found only after the 10th hatching test and it is suggested that the disease is probably not as uncommon in the province as had been supposed.

The ages of the patients were from 1 to 40 years and all but one were males either farmers or country school children. The disease was found along the tributaries of the Yangtze around Chengtu.

The clinical features are listed the prominent manifestations were splenomegaly anaemia, enlarged liver fever and leucopenia, with eosinophilia. Urticaria was present in only two cases. Other tables show the measurements of spleen and liver and the laboratory findings. It is noted that in the acute stage leucocytosis was commonly present.

The patients were treated with injections of antimony potassium tartrate varying in dosage according to the patient size and reaction a sudden drop in the leucocyte count was taken as an indication for immediate suspension of the antimony injections.

The author believe that many of those affected contracted the disease early and that the intestinal manifestations had passed unnoticed.

H. J. O'D. De la-Goffary

HOEIXGSTRIJ, R. P. Observations on the Epidemiology of Infections with *Clonorchis sinensis*. *Trois Rev Soc Trop Med & Hyg* 1949 Mar 14, 4, 5 500-6, 1 fig.

Acute clonorchiasis is rarely seen, possibly because Chinese (Cantonese) and Japanese contribute the great majority of cases and having harboured the infection for centuries they have perhaps developed some degree at least of racial immunity. Hence this account of an acute outbreak on a large scale among nearly 20,000 persons of European origin gathered together in Shanghai under poor hygienic conditions is of no little interest. Illnesses were very prevalent nearly half of the subjects had ascariasis, about one in five had bacillary dysentery and one in ten amoebic dysentery and giardiasis.

The origin of the outbreak, which took place in February and March 1948 was pickled fresh-water fish sold as herrings and eaten avidly. 20 to 30 per cent. of the displaced persons were affected. The clinical picture was that of an acute infection: malaise, chills, fever up to 40°C, anicteric, enlarged and tender liver, eosinophilia from 10 to 40 per cent., in one patient 68 per cent. Faecal examination was positive only after 3-4 weeks, the first symptoms being probably due to invasion of the biliary passages by metacercariae. After a few weeks the acute symptoms subsided, but general malaise and an eosinophilia of 4-10 per cent. remained.

The infection seemed to pass the way for other intestinal infections, for giardiasis, enteritis and *E. histolytica* increased also almost pari passu. Over 7,500 faecal examinations were made in 18 months.

Treatment was not very satisfactory. Certain violet seemed to give some relief and combined treatment with emetine, yarten, carbazone and streptomycin might be useful. Antimony compounds proved very disappointing.

H. Harold Scott

TILLMAN, A J B & PHILLIPS, H S Pulmonary Paragonimiasis *Amer J Med* 1948, Aug, v 5, No 2, 167-87, 4 figs

The authors give a short systematic account of paragonimiasis, and refer to the special features that were noted in twelve cases among Filipino guerrillas in a hospital in Leyte

In five patients, the first onset of symptoms was associated with a febrile attack which was probably malaria when the fever subsided the lung symptoms, cough and haemoptysis, remained and developed The cough was dry at first but rapidly became productive, with 30 to 90 ml of sputum, which was usually "gelatinous, purulent, bloody and of a slightly sour odour in which were scattered dark brown flecks resembling cigarette tobacco shreds" Ova were found in such sputum The cough tended to be worse after exertion and at night Most patients had chest pains Dyspnoea was associated with pleural effusion in three patients Two patients complained of pain in the extremities

Despite the symptoms most patients seemed relatively well Physical signs were present in the lungs at some time in every patient—fine to coarse râles in varying portions of the lungs "Characteristic signs" of fluid were noted in two patients, but fluid was apparently present in four cases An enlarged liver was found in three cases

Ova were found in sputum, faeces and pleural fluid They were found—sometimes not until the 10th examination—in the sputum in all cases, in the faeces in four cases (7 times in a total of 71 stool examinations), and in the pleural fluid in one case

The significance of the blood findings was not clear since all had multiple parasitic infections Eosinophilia was constant in one case only (maximum 8 per cent) was the percentage consistently less than 12 and the maximum was 56 The blood sedimentation rate was above 20 mm in 10 cases In four there was a reversal of the albumin/globulin ratio and in all but two it fell below 2.0 The formol gel test was positive in two cases

Radiological changes were present in every case, there were either massive areas of density, or diffuse, small, soft and usually multiple lesions Both lungs were involved in five patients the right lung and the lower lobes were most frequently involved The lesions diminished during treatment in five cases, disappearing in three

Tartar emetic was given intravenously in 4 cases, it was badly tolerated and had little effect Emetine hydrochloride was thereafter adopted as the treatment of choice Daily injections of 0.06 gramme for 8 or 9 days was the usual course Symptomatic relief occurred in nine cases, usually after the first few injections Constant absence of ova was noted in three cases after repeated courses of emetine The twelve case reports are given in detail [The paper contains much other valuable data, but the reader may be prejudiced by the fact that Sir Patrick Manson is referred to twice as Mason] L E Napier

HALAWANI, A., BASI, I., HAFEZ, A. & SHAWARBI, M. K. Treatment of Tape Worms with Atebrine. *J. Roy. Egyptian Med. Ass.* 1948, Dec., v 31 No. 12, 956-60.

There is no drug which is completely satisfactory for the treatment of a tape-worm infestation. Success in treatment depends on the proper preparation of the patient by complete abstinence from solid food for 48 hours, and proper clearance of the bowel, before the administration of the vermifuge.

A dose of atebrine [mepacrine] of 15 mgm./kilo of body weight given in gelatin capsules or coated tablets after proper preparation, followed within a couple of hours by 1 to 2 ounces of castor oil, or by a large dose of magnesium sulphate, proved effective in removing entire worms with heads from 33 of 53 patients so treated. These worms proved to be both *Taenia saginata* (about 50 worms) and *T. solium* (5 worms). Most worms were evacuated on the day of treatment, but one was passed complete with head on the seventh day after it. The failures in many cases, were probably due to inadequate preparation of the patient before administration of the drug.

Two patients suffered from toxic side effects in the form of vomiting in both cases ascribable to excessive absorption of the drug. J. R. D. ADAMS

PÉREZ FONTANA, V. Origen desarrollo y extensión de la hidatidosis en América. [Origin, Development and Extension of Hydatidosis in America.] *Bolet. Oficina Sanitaria Panamericana.* 1949 Feb. v 28, No. 2, 1-4 56, 1 fig. 4 graphs & 10 charts. (14 refs.) English summary.

The English summary appended to the paper is as follows:—

The report is written in two parts. First, a brief study is given on the biology and morphology of the parasite (etiological agent of the disease (*Taenia Echinococcus granulosus*)) its anatomic dissection and the systemic reactions produced. In the second part the author reviews, historically, geographically and epidemiologically, the development and extension of the hydatid disease in the South American Continent. The disease was probably introduced to America by dogs brought by whalers who settled on both banks of the River Plate and it extended slowly to the neighboring countries. Charts and illustration are presented showing the extension of the disease among cattle and men. Epidemiological and ecological considerations are made with regard to the factors which determine the extension of the disease in the American Continent."

NAUER, L. E. *Strongyloides stercoralis* Infection. Part I. *J. Trop. Med. & Hyg.* 1949 Feb v 52, No. 2, 25-30 1 fig. Part II. Strongyloidiasis among Ex Prisoners of War. *Ibid.* Mar v 52, No. 3 45-8.

L. British workers have regarded human strongyloidiasis as of minor clinical significance but American workers have attributed important pathological potentialities to it. The author now shares their view and has been

further confirmed in it by his observations on ex-prisoners-of-war from the East. *Strongyloides stercoralis* infection, like hookworm infestation, occurs widely throughout the humid tropics, Indo-China, Siam, Burma, and Assam are among the areas of the world most heavily infected.

The life cycle of *S. stercoralis* is characterized by extraordinary variation. The normal infective stage of the parasite is the filariform larva, this develops from the rhabditoid larva outside the host, penetrates the skin or mucosal surfaces, reaches the blood stream and is carried to the lungs, where it penetrates into an alveolus. Here a mature male or female may develop, but more commonly this development occurs only after the larva has migrated up the respiratory passages and descended the alimentary tract to the small intestine. The gravid females, in the mucosa of a bronchus or the mucosa of the gut wall, deposit eggs which rapidly hatch rhabditoid larvae. The larvae deposited in the gut wall normally escape to the exterior in the faeces there to undergo an exogenous cycle, but they do not always so escape. They may remain in the tissues, reach the blood stream and recommence the cycle (direct endo-autoinfection), changing through the filariform stage to the adult in the process. Alternatively they may pass down the gut and develop to filariform larvae within the lumen of the bowel, to repenetrate it at a lower level and so continue the cycle (indirect endo-autoinfection). Again, the larvae may develop to the filariform type in faecal matter contaminating the perianal skin, and repenetrate the skin without undergoing an exogenous cycle (exo-autoinfection). By any of these means the worm infestation of the host may be increased without an exogenous parasitic cycle having taken place, a phenomenon which is unique in helminth infestations.

The exogenous cycle is also subject to variation. The rhabditoid larvae voided in faeces on reaching soil may become filariform and remain as such, now being infective, or they may develop to free-living adult males and females and undergo several such cycles while living in soil.

In view of the variations which may occur in the cycle in man, repeated stool examinations over some weeks may be necessary for the detection of an infestation.

The administration of the usual anthelmintics designed to destroy the parasites in the lumen of the gut is unlikely to be effective, as the worms are located parenterally for most of their parasitic lives.

The pathological lesions due to *S. stercoralis* occur at the chief sites of activity of the worm, viz (1) at the point of entry into the skin, (2) in the lungs and bronchi, and (3) in the intestinal mucosa. Petechial haemorrhages with local inflammatory changes occur at these sites, and the symptoms may be acute and of short duration, or chronic. In heavy infections of the gut there may be extensive sloughing, and ulceration may follow secondary bacterial infection, rarely, ileus or gangrene may follow penetration of the muscularis mucosae by larvae when direct or indirect endo-autoinfection occurs on a large scale. While infections in some cases are symptomless, more commonly there are indefinite digestive disturbances and ill-health, subject to periodic exacerbation. There is almost invariably eosinophilia (8 to 25 per cent) and moderate anaemia. The stools of any patient from a known endemic area, who has suggestive symptoms and eosinophilia, should be thoroughly and repeatedly examined for larvae.

Treatment is unsatisfactory, and gentian violet by the mouth and antimony parenterally would logically appear to afford the greatest hope of destroying the parasites. In practice they have proved of doubtful value. Eventual spontaneous cure occurs as a rule, although the infection may persist for years.

11 Strongyloidiasis is common among ex-prisoners-of-war from the Far East, at least 90 per cent of those infected acquired their infections in Siam,

where it is estimated that between 25 and 100 per cent of the men working on the railway were infected. The symptoms complained of are usually vague and mild, but often are associated with periodic watery diarrhoea. An outstanding and exceptional manifestation however was a periodic transient urticarial eruption first occurring within 12 inches of the anal orifice and often extending to the trunk or thighs. In many cases it resembled the creeping eruption due to *Ancylostoma braziliense* and its linear progress could be followed over a considerable distance at the rate of an inch in $\frac{1}{2}$ to 1 hour. In other cases transitory urticarial wheals appeared. Eosinophilia increased during the urticarial attacks. The attacks have recurred, though at increasing intervals, in some patients over a period of three years observation. Apart from a few cases which have cleared up with large doses of antimony or of gentian violet treatment has proved disappointing. The intensity of the gut infections in these men on the whole has diminished, and there has been no solid evidence of increased worm load due to auto-infection in any case.

The association between these skin manifestations and a strongyloid infection acquired in Siam is 100 per cent. Periodic petechial urticarial, or linear eruptions with a bathing drawers distribution in ex-prisoners from Siam have invariably been followed by the discovery of strongyloids larvae in the stools. The limited geographical area from which men suffering from these peculiar skin lesions were drawn suggested that a distinct species of *Strongyloides* might be responsible: there was no morphological evidence on examination of the parasites that this was the case. The origin of the eruptions may be (1) penetration of the skin by rhabditoid larvae (exo-autoinfection) (2) migration of larvae entering the skin (exo-autoinfection) or even the gut (endo-autoinfection) near the anus (3) allergic reactions precipitated by the periodic systemic migrations of worms or (4) an unassociated infection acquired in the same area. The second explanation seems the most satisfactory in view of the creeping nature of the eruption in many cases, but in no case has a larva been recovered from the lesions.

A. R. D. Adams

CAPLAN J. P. Creeping Eruption and Intestinal Strongyloidiasis.
(Memorandum. *Brit Med J* 1949 Mar 4 389.)

Creeping eruption resulting from exposure to the larvae of certain hookworms is well recognized.

In January 1948 the author noted the occurrence of tortuous urticarial wheals in ex-prisoners of war from the Far East. These wheals usually started on the buttocks and extended upwards towards the iliac crest on to the abdomen and back and down to the middle of the thighs. The lesions were very unstable. They moved at a speed of 5-10 cm. per hour, this is far greater speed than is usually described for creeping eruption. The eosinophil count were usually between 700 and 2,000 per cmm. (10-25 per cent.)

The first man in whom this was observed had worked on the Siam Burma railway and had both a hookworm and a strongyloid infection. The former infection responded to treatment but the latter did not and the creeping eruption persisted. The author observed that this creeping eruption was almost exclusively confined to men who had been prisoners of war in Siam. He found the condition in several hundred of them, and in over 80 per cent he was able to demonstrate a bowel infection with *S. stercoralis*. The identity of the species was confirmed by Professor Buckley. It has so far not been possible to demonstrate strongyloides larvae in the lesion and even presumptive proof is lacking as it has been impossible to find any method of treatment which will eradicate the intestinal strongyloidiasis. The lesion responded to symptomatic treatment with the antihistamine group of drugs.

PAUTRIZEL, R & MAYER, G Les manifestations cutanées provoquées chez le cobaye par injections intradermiques d'extraits vermineux [Cutaneous Manifestations in the Guineapig caused by Intradermal Injections of Worm Extracts] *C R Soc Biol* 1948, Dec, v 142, Nos 23/24, 1551-2

The following is a translation of the authors' summary —

Intradermal injection of clean guineapigs with fractionated ascarid extracts provokes an intense leucocytosis involving all varieties of white cells. Similar injections made on guineapigs previously sensitized with the same extracts result in a considerable eosinophile infiltration, together with modifications of collagen fibres. These eosinophilic infiltrations do not appear after intradermal injections of cestode extracts are made on animals sensitized with nematode extracts

PAUTRIZEL, R & MAYER, G Action d'un antihistaminique de synthèse sur les manifestations cutanées chez le cobaye par l'injection intradermique d'extraits ascaridiens [Action of a Synthetic Anti-Histamine Substance on the Cutaneous Manifestations in the Guineapig caused by Intradermal Injections of Ascarid Extracts] *C R Soc Biol* 1948, Dec, v 142, Nos 23/24, 1552-3

The following is a translation of the authors' summary —

The synthetic anti-histamine substance 3277 R P decreases the intensity of the cutaneous manifestations provoked by intradermal injection of ascarid extracts in guineapigs sensitized to these extracts. In particular, the amount and extent of the leucocytic infiltration are reduced.

PAUTRIZEL, R & BAILLENGER, J Recherches sur l'hémotoxine ascaridienne [Studies on the Haemotoxin of *Ascaris*] *C R Soc Biol* 1948, Dec, v 142, Nos 23/24, 1550

Different explanations have been put forward for the appearance of anaemia in helminthic diseases, a common one being that the worms secrete a haemotoxin but not all authors accept this explanation.

FISHBACK [this *Bulletin*, 1931, v 28, 225] reported the isolation from *Ascaris lumbricoides*, dried in a current of hot air, of a complex which was haemolytic *in vitro*. The present author asks whether this haemolytic complex was not in fact derived from bacteria present in the digestive tube of the worm.

He found that when an aqueous extract of *Ascaris* freshly prepared and stored at 4°C or an aseptically taken specimen of coelomic fluid was added to a red-cell suspension, no haemolysis was observed. On the other hand, the aqueous extract, left at 37°C for 24 hours was able to produce haemolysis. This seemed to suggest that the haemolytic property was related to the development of bacteria.

To test this hypothesis, he isolated bacteria from the digestive tube of *Ascaris* and maintained them on agar. These organisms were members of the *Proteus* group. A freshly prepared aqueous extract was sterilized at 120°C for 15 minutes. This extract had no haemolytic action, even when left at 37°C for several weeks. On the other hand, haemolytic properties appeared within a few hours if the extract was seeded with the *Proteus* isolated from the *Ascaris* itself and incubated at 37°C.

The author concludes that the haemolytic properties identified in extracts of *Leish* by different workers appear to be due to the presence of organisms of the *Proteus* group which are natural contaminants of the extracts.

HENNEY M & HEWITT R. Treatment of Bancroftian Filariasis with Hetrazan in British Guiana. *Amer J Trop Med* 1949 Jan., v 29 No. 1 89-114. [71 refs.]

The result of trials with Hetrazan against Bancroftian filariasis in patients from British Guiana justify some degree of optimism. However in very few cases recurrence of symptoms existing previous to treatment four months after cessation suggests that some adult worms have survived. Reduction in numbers of microfilariae of *B. bancrofti* is invariable with Hetrazan but the degree of the initial microfilaraemia and the amount of drug within the range of 0.5 to 2.0 mgm. per kgm. are of little significance in this reduction. High initial counts (above 100 microfilariae per 60 cmm) are less likely to show a reduction of 100 per cent. on the second day of treatment but this varies in individuals. Few patients showed any microfilariae after one week of treatment and the microfilarial counts remained negative or at low levels as long as follow-up examinations were made (up to 4 months after cessation).

It is believed that the effect of Hetrazan against the microfilariae of *B. bancrofti* is direct since it occurs so rapidly. The systemic reactions which are presumed to be caused by the death of adult worms frequently do not occur until treatment has progressed for one or more weeks and the microfilariae have been cleared from the peripheral blood. No theories can at present be advanced regarding the mode of action of Hetrazan against microfilariae as it is practically ineffective in low dilutions *in vitro* against microfilariae of *L. carinii* and *D. immitis* but does produce an observable *in vitro* effect on the microfilariae of *Toxotia dolacris*. Several puzzling features have been recorded regarding the specificity of Hetrazan for various types of human microfilariae. It is effective against the microfilariae of *O. rotundus* and *L. loa* in the same doses as for *B. bancrofti* but it is not effective against *A. persici* or *M. olandi* in the same doses, though higher doses might be so. If no other effect were produced other than that of rapidly reducing microfilariae in the blood the potential usefulness of such an effect in the control of filarial transmission in endemic areas is obvious.

It is known that Hetrazan has low toxicity in laboratory animals and that comparatively enormous doses are required to produce any evidence of damage. It is rapidly absorbed and excreted rapidly and exhibits no known cumulative effects. In therapeutic doses in man few side reactions have been observed.

Six volunteers, with no worm infections took single doses of from 6 to 10 mgm. per kilo and had headaches nausea vomiting malaise anorexia and lassitude.

The occurrence of pains in various parts of the body temporary swellings localized rashes nodular swellings and the temporary aggravation of pre-treatment swellings during Hetrazan treatment suggest that many of the adult worms were killed. It will be remembered that similar reactions were noted in untreated filarial cases in the S. Pacific area during the recent war and dead adult worms were removed from the sites of nodular swellings (this Bulletin 1941 41 946 1946 43 353).

The site of nodular swellings lymphatic adenitis uveitis, and accompanying symptoms which occur during treatment with Hetrazan may denote the position of the adult worms within the lymphatic. A parallel has been observed that in non-treated cases the exacerbation of symptoms coincided

with the disappearance of microfilariae is brought about by the death of the adult worms. The relative innocuous systemic reactions during treatment with asymptomatic reactions, regardless of the initial degree of microfilaraemia, suggest that these cases were considerably less sensitized to filarial protein than were the remaining groups of cases with histories of clinical symptoms at the time treatment was begun. The fever which occurred in these patients is probably related to the destruction of microfilariae. Polyuria which occurs in both asymptomatic and clinical groups is probably due to a true diuretic action of the drug.

Cutaneous manifestations seemed to respond to anti-histamine treatment with benadryl and ephedrine. The most dramatic and unexpected result of Hetrazan treatment was the partial recession or complete disappearance of pre-treatment swellings in a large proportion of cases. These ranged from partial diminution of swellings and softening of indurated parts to complete recession of swollen glands, swollen arms or legs, swollen spermatic cords and hydroceles, at varying periods during the course of treatment or after it had ceased.

The improvement in advanced cases of elephantiasis after treatment with Hetrazan may invite a complete revision of some of the contemporary conceptions of its pathology.

It is believed by some that the swelling in elephantiasis is due to the obstruction of lymphatics by dead or living filariae, sometimes complicated by secondary streptococcal infections. It is suggested from the effects produced by Hetrazan that the swelling is due, in some cases at least, to the presence of live worms which slowly release a foreign protein and produce allergic reactions resulting in chronic inflammation and oedema.

A part or all of the swelling is reversible after the source of inflammation is removed, even in old chronic cases. The time for the recession differs in different individuals, occurring in two weeks in some and several months after treatment in others.

Symptoms recurring in patients after cessation of treatment have been infrequent so far.

Eight patients have exhibited definite filarial attacks from 16 days to 2 months after treatment was stopped, and in 2 cases swellings recurred after they had been reduced by treatment. It is apparent that in these cases all adult worms had not been killed.

Recurring febrile attacks, subcutaneous nodules and generalized body pains were probably all of filarial origin and responded quickly to treatment with Hetrazan and complete relief was obtained.

During treatment many developed swellings in parts of the body where they had hitherto not existed, but with the exception of two these disappeared completely during the course of treatment. It was suggested that pre-treatment sensitization to filarial protein was intensified by a further increased amount of the same protein. These flare-ups subsided quickly.

These general conclusions are based upon a study of 296 cases of Bancroftian filariasis treated with Hetrazan in British Guiana. Rapid reductions of microfilariae were obtained when oral doses of 0.2 to 2.0 mgm per kgm of Hetrazan were given three times daily. Most cases treated with 0.4 mgm per kgm or higher showed negative counts one week after treatment had started. With a dosage of 0.2 mgm per kgm three times daily for three weeks or longer microfilariae may recur in small numbers at varying times after treatment has been stopped.

Atypical clinical manifestations of filariasis, simulating malaria, arthritis, or cutaneous diseases may be encountered in hyperendemic regions. These frequently respond to Hetrazan treatment.

P. Manson-Bahr

Mazzotti L. Posibilidad de utilizar como medio diagnostico auxiliar en la oncocercosis las reacciones alergicas con-convencidas a la administracion del Hetrazan. [Allergic Signs after Hetrazan as a Subsidiary Diagnostic Measure in Onchocerciasis.] *Rev Inst Salubridad y Enfermedades Trop Mexico* 1948 Sept., v 9 No 3 235-7

In some patients infested with *Onchocerca* cutaneous biopsy is negative in result and nodules may not be present for examination having been already extirpated. Skin reactions and complement fixation tests may give false positives if the subject harbours other nematodes.

The author has observed that administration of Hetrazan (1 diethylcarbamid 4 methyl piperazine) to patients harbouring *Onchocerca* gives rise to allergic phenomena in a few hours—cutaneous oedema and erythema like erysipelatos patches if the eyes are involved they are almost closed by swelling of the lids there is conjunctival congestion axillary and inguinal adenitis, pains in muscles and joints and a rise of temperature to 39 C. The degree of reaction apparently varies with the degree of infection. These reactions were seen in 59 out of 65 patients and they faded within 5 days. These results were not seen when the drug was tried on patients with hookworm, *Ascari*, *Enterobius*, *Trichuris*, *Strongyloides* or *Microfilaria* *ozardi* but IF Bancroft gives a similar reaction. The author concludes that in the absence of this last infection if allergic symptoms follow the administration of a single dose of 4 mgm. per kilo body weight this is a valuable sign of infestation by *Onchocerca*.

De Wit J C De doeltreffendheid van de behandeling van actieve oxyuriasis met vermicifera in de praktijk. [The Practical Value of treating Active Oxyuriasis with Vermicifera.] *Nederl Tijdschr v Geneesk* 1949 Apr 16 v 93 (II) No. 16 1234-40 17 refs.

The English summary appended to the paper is as follows —

"The author has treated two groups of 25 adult and two groups of 40 children suffering from active oxyuriasis with gentian violet and phenothiazin respectively (two cures courses with a three weeks interval followed by control during one year). It appeared that phenothiazin is considerably more effective as a vermicide than gentian violet so that fewer relapses take place. The chances of infection however are so great that after a year 85 per cent of the patients in the gentian violet as well as in the phenothiazin groups were positive again, the number of patient without complaint then amounting to 30 per cent in both groups just as the number of worm carrier without complaints.

"Taking into account that phenothiazin in a dosage of 50 mg per kg body weight still gives light toxic symptoms it seems indicated to reserve this medicament for very serious cases of active oxyuriasis where quick results have to be obtained. However the cures are not permanent the solution of the oxyuris problem has to be sought in hygienic rather than in pharmacological measures."

Larsen J E Jr & Hendrick J R The Probable Explanation for the Difference in the Localization of Adult Trichinella p. m. in Young and Old Mice. *J Parasitology* 1949 16 35 N 1 101-6 10 refs.

Studies are described showing a distinct difference in the localization of adult *Trichinella spiralis* in young and old mice. In young mice significantly greater numbers were found in the posterior one half of the small intestine

(average 69.5 per cent), while the reverse was true in old mice (average 18.7 per cent). Therefore, age apparently is a factor involved in this localization. Approximately the same percentage development of adult worms was found in mice of both age groups, showing no evidence of age resistance.

"In an attempt to demonstrate the mechanism of this difference in distribution, a study was made of the role of intestinal emptying time which is known to differ considerably in young and old mice. A reversal in distribution was shown in young mice by artificially decreasing their intestinal emptying time with morphine sulphate. In this case approximately 95 per cent of the worms were located in the anterior one-half of the small intestine. Although a direct comparison with old mice was not made, these results would seem to indicate that the difference in localization of the adult worms in mice of the two age groups is due chiefly to the difference in intestinal emptying time."

RIEDEL, B. B. Milk as a Source of some Protection against the Acquisition of *Trichinella spiralis* in Mice. *J Parasitology* 1949, Feb., v 35, No 1, 27-30.

"The effect of milk upon resistance of mice toward *Trichinella spiralis* was studied. On the sixth day after parasitism with 100 ± 8 cysts the average numbers of adult parasites harbored indicated that mice fed a commercial ration supplemented with whole milk harbored about the same numbers of adult parasites as mice fed the same ration supplemented with water. The smaller average numbers of larvae harbored 28 days after infection showed that whole milk supplementing a commercial, rat ration prevented many of the larvae from entering the general musculature of the mice."

GURSCH, O. F. Intestinal Phase of *Trichinella spiralis* (Owen, 1835) Railliet, 1895. *J Parasitology* 1949, Feb., v 35, No 1, 19-26, 2 figs & 2 pls [15 refs].

"The results of these experiments demonstrated that in general the greatest percentage of recovery of *Trichinella spiralis* was from the first quarter section of the small intestine, and that the percentage of worms recovered from the following sections declined steadily.

The larvae penetrated the mucosa immediately after ingestion. After 22 and 24 hours of infection, the worms were found again in the lumen. Subsequently, females as well as males penetrated the mucosa and caused extensive destruction of villi.

"After two days of infection, the adults recovered revealed a ratio of two females to one male. Even among those which were eliminated, that is, found in the cecum and large intestine, there were always more females than males."

LARSH, J. E. JR & KENT, D. E. The Effect of Alcohol on Natural and Acquired Immunity of Mice to Infection with *Trichinella spiralis*. *J Parasitology* 1949, Feb., v 35, No 1 45-53.

DEFICIENCY DISEASES

BASSI, G. Some Aspects of Glossitis caused by Vitamin Deficiency. *Internat Ztschr f Vitaminf* Berne, 1949, v 20, No 4, 444-7, 4 coloured figs on 2 pls.

"Glossitis is an important and early sign of vitamin deficiency, pointing to several causes. The least frequent is exogenous deficiency (insufficient intake of

the vitamin) which is practically never observed in Europeans as is shown by the examination of prisoners and internees from German camps. More frequently it is caused by an imbalance in intermediary metabolism in certain pathological conditions caused by, for example diseases of the intestine and the liver etc. Of great importance is deficiency caused by cellular inability to utilize the vitamin through constitutional imperfections particularly in people with hereditary tendencies (sons of syphilitics or alcoholics or mongoloid and negroid types) and in patients with a tendency to splitting of the function tissues. In all these there enters a factor that is neither exogenic nor intermediary but is linked with the peripheral cells ('dergential imbalance').

VALTER R. W. MUELLER, J. F. & REAN W. B. The Therapeutic Effect of Tryptophane in Human Pellagra. *J. Lab. & Clin. Med.* 1939 Mar., v 34 No. 3 400-13 (13 refs.)

Tryptophane in 6 Gm. oral doses induced a remission in typical acute pellagrous lesions.

It caused an increased excretion of N^1 -methylnicotinamide in the urine of pellagrins at a slower rate but in the same manner as in normal persons.

"These observations suggest that tryptophane and niacin are closely related in their role in human as well as in animal nutrition."

SPRUE

STEFANINI M. Clinical Features and Pathogenesis of Tropical Sprue. *Observations on a Series of Cases among Indian Prisoners of War in India. Vallone* 1948, Dec. v 27 No. 4 379-477 4 figs. (23 refs.)

Between March and June 1942, 12,500 Italian prisoners of war were transferred from various stations in India to a camp in Volhangra Valley, where they remained until the beginning of 1946. This camp was situated at 4,000 feet in the Himalayan foothills where the humidity was high, especially during the rainy season, but the winter season from December to February was usually cold and rainy followed by two months of dry weather.

The water supply was classified as oligomineral not containing mica or silicon in excess.

After one year's residence in the area a large number of Italians developed goitre of the parenchymatous type and the number increased progressively even after salt fortified with iodine was obtained. Bacillary dysentery, benign tertian malaria, renal calculus and acute appendicitis were the most common causes of admission to hospital. Surveys of the nutritional status were carried out every six months. The chief complaint was slight continuous loss of weight though no signs of starvation nor of specific deficiencies were observed. Haematological data from 100 persons at random revealed a mild normocytic anaemia.

The first cases of tropical sprue were diagnosed in September 1942 and from then until the end of April 1943 a total of 1,069 cases of varying severity were encountered. Of these 268 were admitted to hospital. The length of time that the prisoners were resident in the area bore a direct relationship to the number of new cases; furthermore the incidence was clearly related to the atmospheric conditions for most of the cases occurred during and after the rainy season. The prisoners aged from 25 to 35 years showed a relatively greater number of new cases and relapses. The most serious cases were found in the oldest age

group, in which 80 per cent of the patients who died were between 50 and 55 years of age

One or more relapses, usually during or immediately after the rainy season were observed in 134 cases (12 per cent). Death occurred in five, from aplastic anaemia. The past history was not helpful. 6 per cent had suffered from bacillary dysentery during the year preceding the onset and 0.7 per cent had chronic amoebic dysentery.

The recent history was rather uniform. Patients usually reported to hospital complaining of severe, uncontrollable diarrhoea, accompanied by distressing meteorism. Other symptoms were sudden severe asthenia, extreme irritability, nervousness and tenesmus. Many experienced difficulty in feeding themselves because of dysphagia.

The first stage of the disease is characterized by fatty diarrhoea and other early signs of intestinal malabsorption. The second is a multiple deficiency picture, while the third is a complex deficiency syndrome dominated by a hyperchromic anaemia typical of the full-blown picture of tropical sprue.

Among the symptoms of deficiency noted in the second stage, glossitis was present in 90 per cent, small aphthae were observed, angular stomatitis with or without cheilosis was recorded in 27, and proctoscopic examination of patients complaining of tenesmus revealed a reddened and congested rectal mucosa. Several patients exhibited exfoliative dermatitis limited to the scrotum, thighs, abdomen, buttocks and dorsal surfaces of hands.

Studies of the haematological picture of 153 patients in the third stage revealed a hyperchromic macrocytic type of anaemia. The other results were as follows —

Mean corpuscular haemoglobin, $\gamma\gamma$	33.8 (20.04)
Mean corpuscular volume, $\mu\mu$	123.34 (94.06)
Volume index (84)	1.47 (1.02)
Mean corpuscular haemoglobin concentration, per cent	31.5 (37.9)
Saturation index	0.92 (1.15)

The values in brackets are calculated from the results obtained in 100 normal persons.

Sternal bone marrow biopsies were performed in 25 cases. With the exception of three, all showed typical erythroblastic arrest indistinguishable from that found in pernicious anaemia.

The serum calcium levels were always below normal, while the serum phosphorus values were within normal limits. Fasting blood sugar levels were consistently lower than normal.

The results of gastric analysis obtained in 97 cases showed mostly hypochlorhydria: there were six with histamine-responsive achlorhydria, and two with hyperchlorhydria.

Fat absorption and distribution of faecal fat were studied with difficulty in twenty cases. The average daily weight of stools was much higher than normal. The fat content was also increased, especially the third stage, but the ratio of split to unsplit fat was not much higher than normal. Despite the slight acid reaction of the faeces it was found that the split fat fraction consisted of soaps.

The average results showed that under the experimental conditions normal subjects absorbed approximately 90 per cent of dietary fat, whereas sprue patients absorbed only 66 per cent.

During the three-year period 112 suffered a relapse during or immediately after the rainy season: of these 23 relapsed each year at the same time.

Autopsies performed in five fatal cases did not furnish any essential information, and postmortem examinations probably do not reveal conditions bearing on the functional derangements underlying the clinical symptoms.

Prognosis was favourable especially when treatment was started early. A large number of cases have been followed since their repatriation to Italy and none has presented any further sign of activity of the syndrome.

Diet and rest formed the basis of treatment. Diet 1 high in animal proteins with protein/fat/carbohydrate ratio (P/F/C) of 1.0/0.23/0.93, was given to patients newly admitted to hospital with severe acute symptoms of the disease. Diet 2, which had a P/F/C ratio of 1.0/0.31/1.48 followed and continued till regression of active symptoms. Diet 3 with P/F/C ratio of 1.0/0.78/2.57 was given to all convalescent patients until clinical recovery appeared complete.

Fatty diarrhoea responded to diet alone. Sulphaguanidine was given to 173 patients in a dose of 4 gm. initially 2 gm. every three hours on the first day and 1 gm. every three hours on the three following days and resulted in arrest of the diarrhoea and a feeling of well-being. Probably the action of the drug consists in suppressing the secondary infections which may be responsible for the severity of the diarrhoea.

Response to liver therapy was satisfactory but less so in the third stage of the disease. Relief from diarrhoea and meteorism was obtained in from 7 to 10 days. Seventeen out of 153 patients did not respond to parenteral liver therapy. This number includes five who developed aplastic anaemia and the four who became chronic. The remaining eight cases who had severe macrocytic anaemia showed only a moderate reticulocyte response until they received transfusion or intramuscular injections of small quantities of blood. Full scale therapy had practically no effect in the 4 chronic cases. The dietary observation confirms the fact that a high protein, low fat diet causes diminution in steatorrhoea probably on account of the lower fat intake so that with diminution of the irritant of fatty material in the intestine diminution of the diarrhoea follows. The impression was confirmed that liver and yeast extract are highly effective.

Behaviour of oedema during treatment presented interesting features. In 43 cases occurrence of reticulocyte response and improvement of the haematological condition were accompanied by an extension of the oedema. Later it regressed with concomitant marked increase of diuresis till it finally disappeared completely in 25 to 30 days. It was found that extension of the oedema, not associated with albuminuria or hypertension was accompanied by a greater temporary fall of total serum proteins. This was possibly due to a greater demand of plastic material for active erythropoiesis. Relationship between hypoproteinaemia and extension of oedema under liver therapy was demonstrated by prompt regression of oedema after plasma transfusions.

The discussion of the results follows on familiar lines and reviews all the recent war time literature on tropical sprue and allied syndromes but does not lend itself to abstraction. It is concluded that dietary deficiency is known to be an important factor in the development of tropical sprue but it cannot be considered the only cause of the disease inasmuch as some peculiarities described in India during the war as for instance the epidemic of sprue in a particular season of the year or its sudden high incidence in military units shortly after their transfer to certain areas could not be explained on the basis of dietary deficiency alone. Local climatic and seasonal factors are therefore important in the pathogenesis of tropical sprue.

ZUCKERMAN, J. L., ZYMARIS, M. C. & VARELA, S. A Simple Method for the determination of Fecal Fat and Fatty Acids. *J. Lab. & Clin. Med.* 1949 Feb. v. 34, No. 2, 282-6.

The method presented yields results in 1 hour after the stool is dry and 40 routine determinations may be performed in a working day.

The procedure is as follows The stool is homogenized and a sample of about 2 gm is dried at 60°C overnight The dried material is pulverized and to a weighed sample (500 mgm) in a test tube with ground glass stopper are added 5 ml of N-HCl, 5 ml of a mixture of petroleum ether and ether (1:1) and 1 drop of 95 per cent ethyl alcohol The tube is stoppered and shaken for 25 minutes and then centrifuged for 15 minutes at 2,500 revolutions per minute The ether mixture layer is aspirated into a weighed beaker, and the extraction process is repeated with 5 ml of ether mixture The solvent is evaporated on a steam bath, and the fatty residue is weighed If free fatty acid determinations are required, the extracted fat is dissolved in 10 ml of ethyl alcohol and titrated with 0.1 N-NaOH

SUAREZ, R M, HERNANDEZ-MORALES, F, MARCHAND, E J, PEREZ SANTIAGO, E & TORREGROSA, M V The Effect of Pteroyldiglutamic Acid (Diopterin) in Sprue *Bol Asoc Med de Puerto Rico* 1948, Oct, v 40, No 10, 282-7

Diopterin is pteroyldiglutamic acid, which has been found to be only slightly active when assayed with *Lactobacillus casei* and *Streptococcus faecalis* The relative potential amount of free folic acid in Diopterin is approximately 77 per cent

The drug was given to six patients suffering from sprue either in the typical acute, or chronic stage in relapse, in doses of 50 to 200 mgm daily All six patients responded clinically and haematologically to the conjugate The sternal marrow also showed the change from a megaloblastic or erythroblastic arrest to a normoblastic stimulation, similar to that observed with folic acid or with parenteral liver extract An interesting observation was the presence of moderate or marked oedema of the legs during treatment and while the patient was showing definite improvement This may be related to changes in the plasma proteins

It appears from this small series that the daily oral administration of 50 mgm of Diopterin is probably an adequate dose in the treatment of sprue, especially when given together with a full sprue diet A capsule of 50 mgm of Diopterin is equivalent to 37.5 mgm of free folic acid.

HAEMATOLOGY

MACFARLANE, R G KING, E J, WOOTTON, I D P & GILCHRIST, M Determination of Haemoglobin III Reliability of Clinical and other Methods. *Lancet* 1948, Feb 21, 282-6, 1 fig [13 refs]

The authors have attempted to estimate the degree of reliability of various methods of estimating haemoglobin The factors that cause the variability in the results are discussed and the experiments were designed so that the effect of

each could be estimated separately, but in this paper they only deal with the total effect. Estimation of the iron content is generally accepted as the most reliable method of estimating haemoglobin and this has been used for judging the reliability of the various methods.

Eight large samples of "normal" blood were taken and divided between 16 representative observers in Oxford and 3 in London. Each of the Oxford workers estimated haemoglobin by 16 different methods, in 8 of which proprietary apparatuses were used and 8 were experimental methods. The instruments used were the Haldane-Gowers, Gowers-Sahli (Helbig), Tallquist, Tintometer, Dare 1, Dare 2 and Sahli-Zetka, and for the experimental methods the wedge colorimeter and the grey wedge photometer. With the two latter 5 different haemoglobin derivatives were used for estimation: carboxyhaemoglobin, cyanmethaemoglobin and alkaline haematin by both instruments, and acid haematin and oxyhaemoglobin each by one instrument. Each member of the London group estimated the haemoglobin by 5 different instruments: Duboscq colorimeter, Duboscq photometer, straight grey wedges, circular grey wedge and Sahli-Zetka. In the case of the first four instruments 4 different haemoglobin derivatives were used.

The results indicate that the dilution methods (Haldane-Gowers, Sahli) are the least satisfactory: differences of 10 per cent or more must be registered before they can be regarded as significant. Whole blood methods are slightly better than the dilution methods. The simple Tallquist is little worse than the elaborate and expensive Dare 1. Dare 2 is slightly better. The Sahli-Zetka is the best of the proprietary instruments.

Of the experimental methods the photometric are better than the colorimetric. The neutral grey photometer with either oxyhaemoglobin or alkaline haematin gave the best results in Oxford, but in London good results were obtained by the Duboscq photometer with all the haemoglobin derivatives and by the straight grey wedge with alkaline haematin and carboxyhaemoglobin. With these combinations differences of less than 5 per cent became significant.

KING, E. J. GILCHRIST, M., WOOTTON, I. D. P., O'BRIEN, J. R. P., JOFF, H. M., QUELCH, P. E., PETERSON, J. M., STRANGEWAYS, D. H. & RAMSAY, W. N. M. Determination of Haemoglobin. IV. A Comparison of Methods for determining Iron Content and Oxygen Capacity of Blood. *Lancet* 1948 Mar 27 474-83. [22 refs.]

The best method of estimating haemoglobin in a sample of blood has been a subject of investigation for many years. The iron content and the oxygen capacity method have been those most frequently used. The accuracy and relationship of these methods has been investigated in London, Oxford, Edinburgh and Cardiff by a number of analysts. Pig, cow and human blood were used in these trials. The iron content was determined by the titanous chloride method and also by potassium dichromate titration and by an α -hydroxyquinoline semi-microgravimetric method. The oxygen capacities were estimated by the Van Slyke apparatus and by the Warburg apparatus. The total haemoglobin was also estimated after reduction with titanous citrate. Both saponin and a synthetic detergent were used for laking the blood. The carbon monoxide capacities were also estimated in Oxford.

Excellent agreement was found in the same specimens among three different analysts (analysts who used anations filter titanous blood titration method for estimating blood iron, a potassium dichromate iron titration technique and a hydroxyquinoline microgravimetric method agree well with the titanous chloride procedure).

" Van Slyke oxygen-capacity results, obtained by three different analysts, agreed and were on an average 3.5% or 0.7 ml of O_2 per 100 ml of normal pig blood lower than the oxygen capacity calculated from iron analysis. For human blood the difference averages 2.0% or 0.4 ml. of O_2 .

" An average difference of 1.1% or 0.23 ml of O_2 was found between Van Slyke oxygen capacity and Ramsay's 'total haemoglobin' method on 14 pig bloods." The discrepancy between the iron and the oxygen methods is thus not entirely due to methaemoglobin which is included in this method.

" The Warburg apparatus may be used to measure oxygen capacity. It is less accurate than the Van Slyke method.

" No advantage was found in the substitution of a synthetic detergent for saponin in oxygen-capacity estimations.

" The carbon-monoxide-combining capacities of 6 human and 3 pig bloods were determined before and after reduction with sodium hydrosulphite. Some of these showed a slight increase in carbon monoxide capacity after reduction, two specimens showed a pronounced difference."

The object of this estimation is to determine the total haemoglobin present, since most temporarily inactive forms are capable of regeneration, the iron-content method is therefore more suitable as the standard base-line for judging the accuracy of clinical methods of estimating haemoglobin. It has the added advantage that it is less subject to fluctuations than the oxygen-capacity methods.

KING, E J, WOOTTON, I D P, DONALDSON, R, Sisson, R B & MACFARLANE, R G. **Determination of Haemoglobin VI. Test of the MRC Grey-Wedge Photometer.** *Lancet* 1948, Dec 18, 971-4, 4 figs [13 refs]

The experiments reported were designed to test the accuracy of the commercially produced Medical Research Council grey-wedge photometer. The experiments were carried out at the Postgraduate Medical School of London, and at the National Physical Laboratory, Teddington. Two instruments were used and 12 observers took part in the experiments.

The photometer is described. Its main feature is an annular grey wedge which is rotated until the light passing through it equalizes the light passing through the coloured fluid in a cell. A monochromatic light filter is fitted over the eyepiece to make this matching possible. It can be used with daylight or artificial light. In the latter case a specially designed lamp is fitted to the instrument.

The results are shown on a histogram, a figure, and a table. The histogram shows that at least 90 per cent of the 120 observations with artificial light fall within ± 2 per cent of the true value and that no individual error is greater than 4 per cent. With daylight the result is almost as good, three observations are 5 per cent above the true value.

None of the eight observers who went through the whole experiment showed any pronounced bias in favour of higher or lower estimates than the true values.

The authors issue a warning that in clinical practice the errors are likely to be larger since in this trial errors associated with the taking of peripheral blood were eliminated by the use of venous blood, and special care was taken in ensuring accurate pipetting and cleaning of the instruments. MED Trop Marseille 1948, Nov-Dec., v 8 No. 5, 707-12. Nomenclature des cellules sanguines. [Nomenclature of Blood Cells.]

A detailed nomenclature prepared by a Committee established by the French Minister of Public Health.

VAGATY J. L. F. & ZAKATY A. F. The Treatment of Polycythaemia Vera. A Record of One Case treated with *Ancylostoma* Infection. *Trans Roy Soc Trop Med & Hyg* 1949 Mar., v 4, No. 3 493-9

A number of methods of treatment for polycythaemia vera have been used none has been uniformly successful. DUPON *et al* (this Bulletin 1940 v 37 598) tried treatment by inducing a hookworm infection the present authors report a case in which this treatment was again tried.

The patient was 55 years of age and had apparently suffered from polycythaemia vera for 10 years when seen by the authors he showed a typical clinical and blood picture of the condition. His stools showed a few *Heterophyes heterophyes* ova only. Between 30th April, 1946 and 14th May, 1946, 650 larvae from a culture of *Ancylostoma duodenale* were applied in drops of fresh water to his hands, feet, abdomen and back and the drops allowed to dry. (On 15th June 1946 200 ml. of blood was withdrawn by venesection to relieve symptoms.) On 23rd September 1946 it was calculated from a stool egg count that he had 32 adult ancylostomes. There was a slight fall in the total red-cell count from 8×10^6 to below 7×10^6 , a moderate leucocytosis (the increase being due to eosinophils which had risen from 1 per cent. to 30 i 83 per cent. Three hundred more larvae were applied to the abdomen between November and December and in February 1947 the egg count indicated 67 adult worms. There was a further drop in the blood count which was now 8 100 000 per cmm. After two more applications of larvae of 250 each to the abdomen in February there was a rise in the egg count which on 14th April, 1947 indicated the presence of 420 adult ancylostomes and a further drop in the blood count to 5 100 000 per cmm. with 83 per cent. haemoglobin on 8th June 1947. The final count on 5th November 1947 showed 5,000 000 red cells per cmm. 60 per cent haemoglobin (originally 140 per cent.) 12,000 leucocytes per cmm. with 27 per cent. eosinophils. There was a corresponding relief of symptoms the man looked and felt better he had no headaches, giddiness, or palpitations and he was more efficient at his work but he was still unfit for prolonged work.

ZIMMERMAN S. P. & DEGGAN, S. Pernicious Anaemia in the Tropical Negro. *Arch Intern Med* 1949 Aug v 82, No. 2, 184-95 (chart R in footnotes.)

1. Ten cases of pernicious anaemia in the tropical Negro are presented.
2. No essential differences were brought out in the manifestations of the disease in Negroes and in other races.
3. Pernicious anaemia does occur in tropical natives, and further study and increased awareness will cause it to be more frequently recognized."

LEHMANN H. Macrocytic Anaemia in Central Africans in relation to *Ancylostomiasis* and other Diseases. *Lancet* 1949 Jan 15 90-93 4 figs. [4 refs.]

Forty-four cases of severe anaemia in Uganda were studied. The patients were all over the age of 17 years and their haemoglobin was below 7 gm. per 100 ml. Control examinations on 77 well nourished Africans showed the blood

pictures of all to be within the limits accepted as normal in Europe and India. Six of the controls had sickle cells compared with seven of the 44 anaemic patients.

The cause of the anaemia in 32 was ankylostomiasis and there was iron deficiency, in six others, this infection was complicated by malaria or a bacterial infection, and in the remaining six the anaemia was due to malaria or bacterial infection and there was no iron deficiency.

The author claims that —

"The macrocytes in Central African anaemia are reticulocytes and young cells in general, emitted by an efficiently functioning bone-marrow into a periphery where constant blood-loss occurs."

He calls these macrocytes "coctic" cells and points out the difference between them and the megalocytes of pernicious anaemia and "nutritional macrocytic anaemia of Wills", the main differentiating features are a low MCHC and the absence of any associated megaloblastic hyperplasia in the bone marrow.

[It is difficult to follow the author's reasoning in the use of the word "coctic" (=fully mellowed), since this is just what these cells are not.]

The pattern of recovery from the anaemia is as follows. At first there is a sharp rise in reticulocytes which is accompanied by a rapid rise in haemoglobin, the MCH and MCV increase rapidly but the MCHC is stationary. At the fourth week the reticulocytes are still high and the haemoglobin is still rising, the MCV decreases and the MCHC starts rising slowly, but the MCH which has reached the normal level earlier remains stationary. At the end of eight weeks there is still a reticulocytosis (4-10 per cent), the haemoglobin is still submaximal and the MCV is still above normal. At this stage a return to normal values will only follow anthelmintic treatment.

"The removal of hookworms leads to darkening of the skin in patients whose iron deficiency has been corrected. It also causes the disappearance of other kwashiorkor symptoms. The possibility is discussed of inhibition by parasites of tyrosine oxidation being the cause of both the pale skin and, at least partially, the escape of coctic cells into the blood-stream. Tests in which tyrosine is injected into the skin are described to support the first part of this theory."

"It is emphasised that the extermination of parasites will have to be an essential measure in the prevention of kwashiorkor."

The author implies, though he does not actually state, that parasitization is more important than malnutrition in the production of kwashiorkor.

RAPER, A B Sudden Death in Sickle Cell Disease *East African Med J* 1949, Jan, v 26, No 1, 14-22 [23 refs]

While much has been written on the sickle-cell trait in America, until recently, little attention has been directed to it in Africa, and this has been mainly to the clinical aspects. The author reports the autopsies with clinical notes in five cases of sudden death, in which he considers that the sickling was the main cause of death.

(1) A child, aged 1½ years, had a short febrile illness and died suddenly. The vessels of the cerebral cortex and medulla were packed with sickle cells and in the medulla there was perivascular extravasation. There was no evidence of meningitis or polomyelitis. Other organs had their vessels similarly packed with sickle cells and the spleen showed the typical sicklaemic lesions.

(2) A child of 8 years with a history of fever and pain in the chest for 5 days became comatose and died on the third day after admission to hospital. The brain cortex was a bright pink. Histological sections showed the vessels packed with sickle cells but no evidence of encephalitis or meningitis.

(3) A child of one year died after three days fever with diarrhoea and vomiting. The right lower lobe was consolidated but had an unusual appearance unlike that of red hepatization. The brain was not examined but other organs had their vessels packed with sickle cells. The vessels in the alveoli of the lung were similarly packed and there were only scanty polymorphonuclears and macrophages but no organisms in the consolidated parts. [The author considers that death occurred at too early a stage to be attributed to pneumonia alone.]

(4) A man aged 23 died 20 minutes after admission. The brain showed extensive blocking of venules with sickle cells with rupture of the vascular wall and extravasation in places.

(5) A young woman, aged 16 years, died suddenly three hours after a forceps delivery with prolonged anaesthesia. Liver and kidney showed sickle cells distending the venules and there were "sickle haemorrhages" in the spleen.

The author points out that the well-known sickle-cell anaemia is only one result of the sickle-cell trait and that persons in whom the trait is well developed are liable to medical accidents as the result of sudden steady sickling of their cells. The precipitating factor he considers to be generalised anoxaemia from any cause e.g. an acute infection prolonged anaesthesia.

The author discusses the incidence of the sickling trait in Africa especially in Uganda. He concludes that the incidence in and around Kampala is about 20 per cent. in children and 10 per cent. in adults. This discrepancy indicates that a large number of the children with the trait do not live to become adults.

L. E. V. PER

DA SILVA, E. M. Verificação sobre a incidência do sickle-cell anemia em índios brasileiros. I. Índios Parikur, Gabilá, Caripuna, Carvelá, Carnujo. [Study of the Incidence of Sickle-cell Anemia in Brazilian Indians. *Mém. Inst. Oswald Cruz* 1948, Mar. 46, No. 1, 125-34, 10 refs.]

The English summary appended to the paper is as follows:—

Research of sickle-cell anemia in 171 apparently full-blooded Brazilian Indians was negative. These Indians belong to seven different tribes.

"Among 166 individuals of Carnujo (Tuland tribe) 3 were sickle-cell (sickle-cell index 1.67). This tribe is very mixed."

In the table above these results are summarized.

"These observations show that sickle-cell test is a useful tool in anthropological investigations."

TROPICAL OPHTHALMOLOGY

A REVIEW OF RECENT ARTICLES LII*

Blindness—An analysis of the causes of blindness in West China was made both aetiological and topographically by SHEN¹. A total of 1,130 blind eyes in 748 patients was investigated. In this series of cases, trachoma is the principal cause of blindness in West China and was responsible for 438 blind eyes. Ulcerative keratitis from various causes occupies the next position and was responsible for blindness in 158 eyes. Keratomalacia is prevalent among the poor and was responsible for 90 blind eyes. The majority of the patients were children under 10 years of age. Only 6 patients were adults. Gonorrhoea is another important cause of blindness especially in infants, and was responsible for 100 eyes. Of these, 66 eyes occurred in adults.

Many babies are delivered by untrained midwives and Credé's prophylactic treatment is not carried out in most parts of China.

Syphilis was responsible for 43 blind eyes. Of these, one alone was due to congenital syphilis and the remainder to the acquired form.

Smallpox and hereditary defects are to-day uncommon causes of blindness in West China.

Trachoma—The discovery of the trachoma agent is discussed in a paper by TABORISKY². This paper was sent by the authors to Budapest in 1931 in competition for the trachoma prize, and has not hitherto been published. The reason why he himself has not published this paper sooner is because his conclusions were based upon facts published in previous articles and he awaited their confirmation by other investigators and also that a single link was missing in the chain of proofs of the aetiological significance of Prowazek-Halberstaedter bodies (PHB), namely the culture of these bodies and their successful inoculation to man and monkey.

It has been admitted that the common bacteria met with in trachoma and the Noguchi bacillus are not of any aetiological significance. The author is of opinion that the elements of the inclusions, the initial bodies (i b) and the elementary bodies (e b) are the infectious agents of the disease. These are known as the Prowazek-Halberstaedter's bodies (PHB) and the elements of these are the virus of trachoma. They are also found in blennorrhoea neonatorum and bath conjunctivitis (inclusion conjunctivitis). The similarity of clinical symptoms and pathological peculiarities in trachoma, blennorrhoea neonatorum and bath conjunctivitis obviously indicates a near relationship of their agents. The difference between these three diseases, the author considers, is only one in virulence such as between variola and vaccinia. Blennorrhoea neonatorum and bath conjunctivitis are mild diseases without complications, clearing up even without treatment, while trachoma is a long and severe illness with frequent complications requiring prolonged treatment.

The particles of trachoma virus, the e b, differ from the e b of psittacosis and lymphogranuloma in their size and mode of staining and particularly in their biological properties. Thus a specific organism is found in trachoma which is not to be found in other diseases, according to the first postulate of Henle-Koch. There remains the question whether the PHB are present in all or only in some of the cases of trachoma. The whole course of the disease offers conclusive signs of the close connexion between the inclusions and the clinical symptoms of trachoma. The presence and disappearance of the PHB depends

*For the 51st of this Series see Vol 45 pp 1109-1112

² TABORISKY J. The Discovery of the Trachoma Agent. Acta Med Orientalia 1948, Apr v 7 No 4, 61-71, 2 figs [Numerous refs]

on (a) the time passed from the beginning of the disease (b) the severity of the disease and (c) the treatment. In medium and severe cases the PIB are always found in the first months of the disease in spite of every treatment. The inclusions disappear when the disease becomes regressive or remains stationary. If the virus becomes active again the inclusions may reappear. As to the third postulate of Henle-Koch namely the growth of elements of PIB in culture and their transmission to man and animals, no positive results have so far been obtained. [See MACCHIARELLO this Bulletin 1948, v 45 111*]

The campaign against trachoma in Morocco is discussed by DELANCO². He came to the conclusion that eye washes and ointments were of little use in treatment and he sought a remedy to attack the actual organism of the disease. He found that the granulations were identical with those found in tuberculosis and akin to those found in leprosy. He has employed local treatment by applying chamomogra oil to the granulations and found even after the first application that improvement was apparent within a week. Pain, photophobia, blepharospasm and inflammation all became less. In the course of time the granulations became smaller and ultimately disappeared.

The treatment is painless, easy to carry out and the cost is trivial.

The author published his first paper on the treatment of trachoma by local applications of chamomogra oil in 1925 [this Bulletin 1928, v 23 920].

A statistical study of trachoma among in-patients is discussed by CHU³ in Chengtu. Of 2,903 patients admitted to the Department of Ophthalmology of the Chengtu Eye Ear Nose and Throat Hospital from January 1940 to December 1943 1,503 patients, i.e. 44.9 per cent., were diagnosed as having trachoma. The sex ratio was 54.6 per cent. females to 45.4 per cent. males. The ages of the patients in 85.1 per cent. of cases ranged between 16 and 40 years of age. The majority of the patient had trachoma stage III (MacCallan) nearly all of the cases showed some sequelae and 31.9 per cent. were classified as blind on admission. The most important factor as a cause of blindness in trachoma, was a lesion of the cornea and so to reduce the incidence of blindness it is essential to control the spread of trachoma.

CHAU⁴ presents a set of figures on trachoma among the in-patient of the same hospital for the year 1939 to 1939. These figures are supplementary to those published by CHI and are analogous. He points out the high incidence of keratitis as well as trichiasis and entropion in trachoma stage III. He further calls attention to the frequent association of entropion or trichiasis with keratitis and that trichiasis or entropion are usually bilateral.

Leprosy—Lagophthalmos in leprosy is discussed by CHATTERJEE and DHARMENDRA. The condition is sometimes seen in leprosy and more frequently in the neural than in the hypomatous type and often leads to complications such as conjunctivitis, keratitis, corneal ulceration, leucoma with pannus, thalmitis and phthisis bulbi. The condition and its complication as well recognized but what is not always appreciated is that they are often preventable by timely treatment.

Lagophthalmos is caused primarily by paralysis of the orbicularis oculi and possibly the deformity is later exaggerated by the unopposed action of the levator palpebrae superioris muscle. In more advanced cases the orbicularis oculi is completely atrophic and the eyelid are fully retracted.

CHATTERJEE	S N & DHARMENDRA	Lagophthalmos in Leprosy	Leprosy in India			
1947 Apr		19 No 41	6 749-50 4 p's			

It is usually associated with a leprous lesion on the affected side involving the eyelids and the adjoining skin. In a lepromatous case the lesion is in the form of a diffuse infiltration or nodulation and paralysis is sometimes noticed when the lesions subside. In a neural case the skin may be hypopigmented and flat or red and thick. It may be or may not be anaesthetic but sensation of pain on pin-prick is diminished in all cases.

Lagophthalmos may be present when the patient first attends for treatment or it may occur later during the course of treatment. Lesions on the face and eyelids do not always give rise to lagophthalmos. It may or may not be accompanied by loss of sensation of the conjunctiva and cornea, and the anaesthesia may be found before the lagophthalmos sets in. It is responsible to a certain extent for the associated conjunctivitis and keratitis, since it interferes with the natural defensive mechanism of the eye by allowing foreign irritating particles to remain unnoticed in the tissue. When lagophthalmos supervenes, the defensive mechanism is further interfered with and the result is constant irritation causing conjunctivitis, keratitis and ulceration of the cornea, which may lead to leucoma or panophthalmitis.

The treatment of lagophthalmos consists in prevention as well as cure. Unless there are present signs of reaction, all cases of leprosy with lesions in or around the eyelids should receive preventive treatment on the following lines —

Injections of creosoted hydnocarpus oil should be given around the orbit including the eyelids. The injections are given by the intradermal method once in three weeks. In the interval, weekly injections of the oil are given in other lesions if there be any, or intramuscularly into the buttocks. The injections are continued until the lesion fades and there is partial return of sensation. When the conjunctiva and cornea are anaesthetic, the affected eye should be protected by using tinted goggles and liquid paraffin is frequently dropped into the conjunctival sac to counteract the effects of drying.

The curative treatment of lagophthalmos has to be on the same lines as the preventive treatment but has to be more vigorous. The hydnocarpus oil is better injected subcutaneously. About 1 cc of the oil can be injected in the eyelids once in three weeks at one sitting. The treatment should be continued for some time after the correction of the defect, so that the results obtained may be maintained. Liquid paraffin should be dropped into the eyes frequently and if there be no ulceration the affected eye should be bandaged at night. If ulceration of the cornea occurs, it should be treated with atropine drops or ointment and a pad should be applied. When there is not much discharge, the affected muscles should be massaged daily for about half an hour and the patient should be instructed to move his eyelids frequently.

With this treatment lachrymation diminishes and there is a gradual return of power to the affected muscles within three months. In advanced cases the surgical treatment of lateral tarsorrhaphy or canthorrhaphy should be combined with medical measures.

A report of leprosy lesions of the fundus in a case of lepromatous leprosy of fifteen years duration is discussed by ELLIOTT⁷. The patient, a corpulent white male, 43 years of age, reported to the eye clinic complaining of sudden loss of vision in the left eye. He had been reading when he became aware of this difficulty and when seen two hours later had no other symptoms except slight discomfort. Upon examination there was slight circumcorneal injection. The pupils were active. The fundus presented an array of creamy white, waxy-surfaced, pedunculated "pearls", projecting from the retina and situated

⁷ ELLIOTT, D. C. A Report of Leprosy Lesions of the Fundus. *Internal J Leprosy* 1948, July-Sept. v. 16 No 3 347-50, 1 fig.

from one to two disc diameters from the optic disc. In all there were two such lesions and they were identical ophthalmoscopically with those seen at the iris in this patient and in others. Iris lesions of this kind have been histologically proven to be true lepromas and contain typical lepra cells, Hansen bacilli and round-cell infiltrations. In this patient lepromata of the iris were present in each eye but the retinal lesions were found only in the left eye. During observation it was found that these iris and retinal lepromata were transient formations developing and receding within a period of eight months duration.

This was the only case of a retinal leprous lesion in the examination of over 500 fundi.

In an addendum the author states that since this article was written three other cases of leprous lesions of the fundus of the eye have been demonstrated.

Vitamin B deficiency.—The article by DAWSON FOXLEY & WARD (this Bulletin 1949 v. 46, 278) on vitamin B complex deficiency states in West Africa is discussed by Fitzgerald Moore*. He points out that the dietaries of the Gold Coast, Sierra Leone and Southern Nigeria differ markedly in the staple foodstuffs and, as would be expected, in the expression and symptomatology of deficiency disease. Again only certain sections of the peoples show manifest evidence of these conditions and the severity of them is primarily determined by economic circumstances. Generally speaking the Gold Coast is much less affected with frank nutritional disease than is either Sierra Leone or Southern Nigeria. Though kwashiorkor is more common in the Gold Coast, neither the very extensive dietary and clinical survey of PERCIVAL POPE of BEATRICE RUSSELL have recorded any real incidents of nutritional retrolbulbar neuritis there in great contrast to these other two colonies.

Nutritional retrolbulbar neuritis (followed by partial optic atrophy) can occur independently of either beriberi or arboflavinosis or along with these diseases and the signs of these two latter will rapidly disappear with the return to a normal diet but not so the central neuritic condition. In Southern Nigeria beriberi is a practically unknown even recorded disease. Arboflavinosis was extensively common among the manioc eaters and associated with it, nutritional retrolbulbar neuritis (in the active phase). Arboflavinosis was however not seen among the yam eaters who only used manioc—a secondary staple foodstuff. The degree of arboflavinosis varied considerably and in Nigeria was not as severe as among the rice-eating population of Sierra Leone. For example, frank keratitis was rarely seen in Nigeria, but was exceedingly common among the Sierra Leone sailors and Luo boys. The incidence of nutritional retrolbulbar neuritis in relation to arboflavinosis varied considerably. The highest rate found by the author was 1 per cent. By contrast a high percentage of pregnant women attending the ante-natal clinic in Lagos showed arboflavinosis but it was rare to find nutritional retrolbulbar neuritis.

H. H. SCOTT showed in the central neuritis of Jamaica that beriberi was not present in those cases. WRIGHT described the A and B avitaminosis of Sierra Leone and considered that the condition was apart from beriberi. Likewise the work of STANFORD and many others does not support beriberi as a cause of retrolbulbar neuritis. Thiamin was found of little value in nutritional retrolbulbar neuritis in prisoners of war camps, both in its failure to cure and to prevent the condition. The author in Nigeria was successful with autoclaved marmite which was as efficient as ordinary marmite always provided the cases were seen early enough. The aetiology of nutritional retrolbulbar neuritis both as regards the exact curative or preventative factor or factors is still not known. It is possible the cobalt-containing vitamin B₁₂ which according to

SPIES, possesses a powerful antineuritic effect, may provide the solution. It is also possible it may not be a vitamin at all, but that "something else" in marmite and yeast and still unidentified.

Thelaziasis—*Thelazia* infestation of the conjunctival sac in China is reviewed by LIANG⁹. He gives the history of four cases reported by others and describes a fifth case seen by him. All the cases were caused by *Thelazia callipaeda*. Animals infested with *Thelazia* are known to be widespread in China and the worm may involve the eyes of mammals and birds. *Thelaziasis*, as do other parasitic diseases, produces an eosinophilia in the blood. When present in the conjunctival sac it produces symptoms of foreign body irritation, intense pain and lachrymation and causes verminous conjunctivitis. The cornea may become cloudy as a result of irritation by the worms. Occasionally there may be no subjective symptoms in the infected eye, the parasites being discovered during the routine examination.

HEAT STROKE AND ALLIED CONDITIONS

MOV, A. M. El empleo de la protección antisolar y de los repelentes de insectos en los indígenas latinoamericanos [The Use of Insect Repellents and Anti-sunburn Substances among the Latin-Americans] *Rev Argentina de Dermatosisifilologia* 1948, July-Dec, v 32, Nos 3/4, 303-6 [35 refs]

Hernandez is quoted as having mentioned, nearly 380 years ago, that the Mexican Indians used an aromatic resin, believed to have been *Liquidambar styraciflua*, as a protective ointment. Substances in later use have been obtained from *Bixa orellana* and having many synonyms according to locality (more than a dozen are mentioned), one of these is *urucu*, and the medical term for anointing the body with the red juice is *urucuzation*.

An analysis of the seed of *Bixa orellana* by Chevreuil in 1833 showed it to contain a water-soluble yellowish colouring matter, *orellina*, and a red substance, *bixine*, soluble in oils. It is the latter which is used as an ointment with a fatty basis, either animal as capibara, iguana, or fish oil, or vegetable as palm oil. It is used as a protective from the sun's rays and also as a repellent of insects, especially mosquitoes. Being insoluble in water it is not affected by sweat. The women anoint the men with it before the latter go to work in the sun, or to hunt or fish, and "they return from fishing in a canoe with their backs covered with dead mosquitoes". The seeds are also used medicinally as a laxative and as a condiment with rice.

The experiment was made of exposing three thermometers to the sun, one had the bulb silvered, another was covered with *urucu*, the third had the bulb blackened. The first gave a reading of 32°C, the second 33°C, the third 40°C. *Urucu* therefore protects against the sun's action, both the heat and the actinic rays, but does not prevent the evaporation of sweat.

In drier and colder regions where *Bixa orellana* does not grow, or grows only with difficulty, infusions of the bark of certain trees of the *Simarubia*, *Simaba* and *Picrasina* genera are used as repellents.

H Harold Scott

⁹ LIANG S C. *Thelaziasis of the Conjunctiva*. *Chinese Med J* Chengtu Edition 1945, Jan, 1, 631 No 2, 70-72.

days the first second third and fourth stage larva required respectively 5.7-6.2 days, 4.3-4.4 days, 5.3 days, and 9.0 to 9.4 days. A slightly better survival rate for the *fipiens* larvae was not found to be statistically significant. [No observations for pupae are given at this temperature.] Emergence from pupae occurred at 18.1°C. in both species and, at this temperature both were fed on pigeon within three days and laid fertile egg rafts nine to twelve days later. It is concluded that at low temperatures no appreciable differences were observed between these strains of *C. fipiens* and *C. quinquefasciatus* as regards survival and the rate of development of the aquatic stages nor in the feeding and mating habits of the adults.

Five-minute exposures of the aquatic stages of all four populations to high temperatures showed that the lethal temperatures for 50 per cent. kills varied only within the narrow ranges of 42.1 to 43.0°C. (for eggs) 41.3 to 42.3°C. (larval stages) and 41-42°C. (pupae). The duration of the various stages bred at high temperatures (31-34°C.) were as follows: 23-24 hours for the eggs, 1 day for each of the first three larval instars, 3-4 days for the fourth instar larva and 24 hours for the pupae. Eggs hatched at 33°C. but not at 34.5°C. There were no appreciable differences in the survival rates of these various stages and 16.5 per cent. of *C. fipiens* and 17.7 per cent. of *C. quinquefasciatus* matured to adults. Adult activity at 31.5°C., 32°C. and a relative humidity of 93 per cent. was studied for *C. fipiens* (Michigan), *C. quinquefasciatus* (Alabama) and the southern form of *quinquefasciatus* from Texas. Females of all three populations fed on pigeon but only the Texas form of *C. quinquefasciatus* produced seven completely fertile egg rafts, the other strains producing four out of five (*fipiens*) and seven out of eight (*quinquefasciatus*) infertile rafts. The fertility of the raft increased, however, when both these strains which still included males were transferred to room temperatures (temperature not stated but presumably moderate) the conclusion being drawn that at the high temperature mating had not occurred with normal success. It is concluded that apart from this indication that the Texas population of *C. quinquefasciatus* mates more readily than *C. quinquefasciatus* from Alabama and *C. fipiens*, no appreciable differences were observed at high temperatures between *C. fipiens* and *C. quinquefasciatus*.

All four populations paired on the wing, mated in 5 in. scale cages, and were autogamous, requiring blood meals for the production of fertile eggs.

Cross-matings between all four populations resulted in fertile progeny, and in the case of both types of pairing of *C. fipiens* (from Michigan) and *C. quinquefasciatus* (from Alabama) the hybrid stock was bred to the egg of the F_2 generation. All other crosses were maintained as far as the eggs of the F_2 generation. Sterile rafts were rare.

The author gives reasons for suggesting that the absence of *C. quinquefasciatus* in the north is due to its inability to hibernate or to withstand more than about a hundred days of North Carolina winter conditions, possibly a reluctance to mate at low temperatures also plays a part in limiting its northern distribution. Hibernation enables *C. fipiens* to survive the colder northern climate and its absence in the south may, it is suggested, be due to its inability to mate satisfactorily at high temperatures.

It is observed that in nature transitional forms between *C. fipiens* L. and *C. quinquefasciatus* Say have been reported by many workers and, in view of this, and of the results obtained in cross-breeding the four populations dealt with in the present study, it is suggested that the differences between the species are no more than intra-specific. The following nomenclature is therefore proposed: *C. fipiens fipiens* L. 158 from Michigan and Baltimore, *C. fipiens quinquefasciatus* Say 1822 for the *C. quinquefasciatus* population from Texas, the *quinquefasciatus* population from Alabama occupies an

ticks fed under a variety of conditions. They show that for a very wide range of values a linear relationship between the logarithm of the blood area-concentration and the mean reciprocal survival time of the ticks has been demonstrated. This was not altered by treatment of the rabbits with B.A.L.

REPORTS SURVEYS AND MISCELLANEOUS PAPERS

COLONIAL OFFICE. Report on the Water Resources of the Bechuanaland Protectorate, Northern Rhodesia, the Nyasaland Protectorate, Tanganyika Territory Kenya and the Uganda Protectorate (DRAKSHAM F). Colonial Research Publications (No. 7). 85 pp., 3 diagrams, 14 maps (4 folio) 3 graphs & 24 figs. on 8 pls. 1948. London. H.M. Stationery Office [10s. 6d.]

The scarcity of water throughout a great part of East and Central Africa is a matter of every-day knowledge. The astonishing feature of it is that by the standards of many other parts of the world the actual rainfall is quite adequate and countries with no greater precipitation support dense flourishing populations, whereas in these parts of Africa populations are restricted. The difference lies partially but not very greatly in an unfavourable annual distribution of rain in Africa, and very much more in a wasteful use of the land over centuries which has led to soil erosion, a quick run-off in the rain, and general aridity very soon after them. Ignorance of how to conserve water or even how to tap natural sources is a contributory factor to such an extent that Gillman in his survey of population distribution declared that the presence or absence of a permanent domestic water supply within the reach of primitive tools and skill determines the pattern of population.

Improvement in the availability and use of water are more likely to benefit the African than almost any other measure and they are of direct medical and demographic interest. The author has surveyed the resources and made a series of recommendations of which the most important is the promotion of small schemes of conservation on a village scale by such measures as the impounding of headwaters, the construction of wells, improvement of dams (a form of swamp) and modification of springs giving detailed examples of their working. He is to some extent concerned at the risk of increasing the prevalence of disease particularly malaria, hookworm and balharzia. The reviewer is naturally anxious that this should not happen but as he sees the problem the usual alternatives are not healthy or unhealthy people but poor or no people, the new communities to be created by the measures now advised would not in any case start on a worse basis than those that now exist and steps could readily be taken to improve their lot.

In the standard scheme for a village of 100 persons with 100 head of stock, the author considers that a daily supply of 1,500 gallons would be adequate and that it could best be secured from a catchment area of 200 acres collected in a small reservoir which would be controlled by a dam 70 feet long, 50 feet broad, 5 feet average and 12 feet maximum depth. This would be protected from direct access and the water would be led through piping and channels to an appropriate water point. The reviewer's reaction is that this is in

reality demanding very efficient conservation as such a community might often have little more than 300 or 400 acres at its disposal, and he would therefore like to have seen less emphasis in the report on the possibility of using makeshift piping and conduits which could only cause great wastage. For evidence that the scheme is in fact practicable in its broad outlines one can turn to the ancient irrigation works of Ceylon, some of which are now being revived, which by a great multiplication of works of this sort supported more people than do the countries now surveyed, despite the fact that the rainfall was about the same and the land available one fortieth of that now considered.]

G Macdonald

SAUNDERS, I G. A Survey of Helminth and Protozoan Incidence in Man and Dogs at Fort Chipewyan, Alberta. *J Parasitology* 1949, Feb., v 35, No 1, 31-4

Fort Chipewyan is at the west end of Lake Athabasca, about 370 miles north of Edmonton, Alberta

In the course of other investigations there during the summer of 1945, the author found evidence of human tapeworm infection and accordingly examined stools from as many persons as possible who had lived at least a year in the north. For practical reasons, most of those examined were children at the Mission School

In all, 140 persons were examined by direct examination of a simple smear. The results included 4 specimens positive for *Entamoeba histolytica*, 10 for *Iodamoeba bütschlii*, and 19 *Giardia intestinalis*. No *Taenia* infections were found, nor were trematodes or *Ascaris*. No diagnostic facilities for *Enterobius* were available, though histories of many persons suggested its presence.

The only helminthic infection positively identified was *Diphyllobothrium latum*. Ova were present in 16 of the 140 persons. Symptoms were few and vague and most of the infected persons were apparently unaware of their infection. No anaemia attributable to fish tapeworm was encountered. Eight persons were treated with castor oil and male fern, without evidence of toxicity.

The author discusses the factors affecting the incidence of *D. latum* infection in this area. "The people are essentially nomadic, with 'makeshift cooking conditions'. This factor would not apply in the case of the children in the Mission School. It was possible to examine only 16 of the persons known to lead the nomadic life and 11 of these were positive for *D. latum*. Indifference and suspicion made it difficult to obtain specimens from these people and even in the willing persons constipation, which is common, added a further complication.

The distribution of *D. latum* further north is discussed and from local information the author has reason to believe that the infection is "probably distributed all through the vast north country."

It is also noted that 38 of 88 dogs examined harboured *D. latum*, but usually only a few ova were found. *Ancylostoma caninum* was found in 10 dogs and a cyst of *Isospora* (probably *bigena*) in one.

[In connexion with the finding of *E. histolytica* in 4 human cases, the author writes: "Having no concentration or staining checks on the direct iodine smear observations, the author reports with some hesitancy the incidence of *E. histolytica* so much farther north than any previous records. It was a small-cyst race encountered occasionally in Saskatoon (Miller 1939), non-pathogenic, and was in Indians and half-breeds, not whites who might have been infected outside"]

BOOK REVIEWS

MATRAXO Flávio & others. *Tratado de Leprologia*. [Treatise of Leprology. Vol. 1. História da lepra no Brasil e sua distribuição geográfica [MATRAXO F.] 208 pp., ill. Vol. 2. Etiopatogenia e anatomia patológica [ROTHBERG A. & BECHELLI L. M.] 451 pp., ill. Vol. 3. Diagnósticos [DE SOUZA LIMA L. & DE SOUZA CAMPOS V.] 168 pp. ill. Vol. 4. Clínica e terapêutica [BECHELLI L. M. ROTHBERG A. & MATRAXO F.] 368 pp., ill. Vol. 5. Epidemiologia e profilaxia [DE SOUZA CAMPOS V. BECHELLI L. M. & ROTHBERG A.] 397 pp. ill. 1944. Rio de Janeiro. Serviço Nacional de Lepra.

Several monographs on aspects of leprosy written by well-known leprologists, have been issued by the Brazilian Health authorities. Now at the instigation of the National Leprosy Service under the Director Dr Ernani Aguiar, these writers have combined to produce a Treatise on Leprosy. This treatise consists of 5 volumes bound in two. 1. History of Leprosy in Brazil and its geographical distribution. The latter is dealt with again and more fully in Vol. 5. 2. Aetiology and Pathology. 3. Diagnosis. 4. Clinical description and Treatment. 5. Epidemiology and Prophylaxis.

Though published as long ago as 1944 this work must still be the most comprehensive in existence on this disease. The lack of comprehensive works in Portuguese and the difficulty of acquiring papers and books published abroad led, says the writer of the preface, to the preparation of the monographs referred to above but in 1942 the decision was reached to combine in the form of a treatise the various articles for the information of medical men engaged with leprosy and its prophylaxis in all States of the Federation. So in 1943 the National Leprosy Service was instigated to prepare four more sections (one on *Diagnosis of clinical laboratory and biological* has already been issued in 1944) and to produce them complete in the form of a Treatise.

The work, though dealing primarily with conditions in Brazil, will be of enormous value to workers in any country where leprosy is rife. Thanks are due therefore to the Public Health Service of the Ministry of Education and Health in Brazil under the Minister Dr Gustavo Campana and to the Institute of Inter American relations of the United States. In the space of our disposal we can do little more than indicate the scope of this large work of nearly 1 000 pages.

Volume I *History and Geographical Distribution* is divided into 4 parts. Part I gives an account of the history of the disease and comprises three chapters. The first discusses the origin of leprosy in Brazil and states that it was not indigenous but was introduced by slaves from Africa and by the Portuguese from Europe. The second tells of the social and economic factors which caused the infection to spread over the country especially by agency of the leprosy in the third the extension is described in more detail in each of the 22 constituent States of the Federation—a very interesting chapter tracing the increase from earliest times down to 1943. Part II also contains 3 chapters one on the study of the disease in Brazil, started by Gomes in 1788. The second is a review of the epidemiology, treatment, the clinical aspect and pathology—merely a long list of names and dates. The third contains a short account of the spas reputed to be beneficial in treatment and of vaunted charlatan remedies. Part III speaks of the habits and social customs of patients, mendicants, their isolation, hospitalization, segregation and the ban against them. Part IV deals first with official measures put into force in the colonial period, 17th to 18th centuries then in imperial times to the present with references to philanthropic and religious societies concerned with sufferers from leprosy. Following this is a sketch of scientific measures in the anti-leprosy campaign in the various

States and the co-operation between the State authorities and Societies for combating the disease. There is an appendix to this chapter, of documents of historical interest.

Volume I is interesting but is, naturally, not so full and detailed as Professor de Souza-Araujo's large and comprehensive work on the *History of Leprosy in Brazil*, two volumes of which have already appeared and have been reviewed in this *Bulletin* [1947, v 44, 760, 1948, v 45, 1132].

Volume II, on *Aetiology and Pathogeny*, describes in 11 chapters the organism, its characters, the attempts at cultivation (this section is well illustrated), the relations between human and rat leprosy, the results of inoculation into rats, buffaloes, birds, opossum, cattle, sheep and horses, the possible hereditary or congenital transmission, the mode of penetration in man and its spread after gaining entrance, immunity and allergy, the lepromin reaction and the reactions to syphilitic antigen and to other acid-fast cultures, and the Witebsky-Klingenstein and Rubino reactions. Finally, accessory factors are considered, such as age, sex, nutrition, climate, other diseases and individual and racial predisposition. [Unless the editing of a large work such as this is very carefully done there is a danger of overlapping and repetition, and this last section is discussed again in the final volume of this treatise.]

The section on *Histopathology* comprises six chapters and is embellished with fine reproductions of photomicrographs of the tissue changes set up and in it are discussed the relations between the pathology and the clinical manifestations, the factors determining the mode of evolution and the course towards cure or death.

Volume III, on *Diagnosis*, is of the highest importance. The subject is treated from several aspects: (i) Clinical, the physical examination and the results of the histamine and pilocarpine tests; (ii) Bacteriological, the search for the organism in the nasal mucus, the skin lesions, the glands, the peripheral blood by thick drop and the Crow and the Rivas methods, the nerves and the secretions or excretions; (iii) Serological, the reactions of Rubino, Gomes, Lleras Acosta, Witebsky and others; (iv) Histological and Immunological, Mitsuda, Bargher, etc. Diagnosis of nervous leprosy is gone into in more detail and the differential diagnosis from syphilis, pityriasis, vitiligo, forms of eczema, various erythematous and achromic dermatoses. Tuberculoid and lepromatous types are similarly discussed. This section is well illustrated, some of the reactions being reproduced in colour.

Volume IV comprises two parts: 1 *Clinical*, 2 *Therapeutic*. The former is a splendid effort well carried out. All forms and aspects of the disease are described and depicted with excellent photographs, many coloured plates and with abundant references. Coloured plates showing the development of lesions of the nasal septum are remarkably good. The treatment section occupies less space as is but natural since there is not very much to say on this subject. The treatment proper is prefaced by general remarks on appraising the results and warning against too ready acceptance of the *post ergo propter*, because good hygiene will bring benefit and the disease presents at times spontaneous remissions so that amelioration after a certain treatment is not proof that the one is due to the other and the crucial test consists in observation of control cases equal in number and stage and under similar conditions, untreated. Mention is made of treatment by improved general hygiene, by good food and properly balanced diet. Modes of treatment now little used are referred to: iodides, arsenicals, mercury, copper and gold salts, sera, vaccines, vitamins, sulphonamide drugs, diphtheria toxoid and antitoxin, carbonic acid snow, methylene blue, eosin and other dyes, phenol, thymol, guaiacol and several more. Lastly, in greater detail, chaulmoogra, the oil, the ethyl esters and fatty

acids. This book was published in 1944 (but received here only in 1949) and although Promin is mentioned, the remarkable results achieved in treatment by the Sulphonas since that time are of course not mentioned. Special short chapters deal with treatment of the leprosy reaction and the many drugs which have been tried for it—of perforating and other forms of ulcer and the pain of the disease. The last few pages of this volume are given up to consideration of the part played by physiotherapy, mechanotherapy and hydrotherapy including galvanism, high frequency diathermy, U.V. rays, balneotherapy, massage, physical exercises and gymnastics.

Volume I deal with *Epidemiology and Prevention*. Under the former heading are considered biological and social factors, climate, war, migration. The distribution and figures of prevalence based on censuses made in 1940 onwards and analyses of earlier records are given for the different States of Brazil, for South, Central and North America, Canada, the European nation, Asia and the Far East, Oceania, East, West and Central Africa, Egypt and the Sudan. Tables are presented to show the same more graphically. Other factors already referred to in Volume II, such as sex, age, occupation, race, climate, nutrition, general hygiene and sanitation, intercurrent disease, spread of infection in the family and factors favouring dissemination are all in turn debated, though some only briefly.

Lastly, Prophylaxis in antiquity and in more recent times—periodic examination of contacts and associates, isolation, hospitalization, asylums, colonies, sanatoria, domiciliary segregation, rules for discharge, dispensaries for ambulant and probation patients, propaganda and educational measures, organization of a leprosy service, all come under discussion ending with an account of the National Leprosy Service of Brazil and what it has succeeded in accomplishing and at what cost in each of the constituent States, the laws at present in force and additional laws proposed for adoption in the future.

The Minister of Health, the National Leprosy Service, the Editor and the contributing authors are all to be most heartily congratulated on accomplishing their huge task and producing a work which must surely be a standard of basic information for many years to come. Nor must we forget the producers and publishers. The whole set-up of the work is high class. The print is clear and easy to read, the paper of a quality we have not seen for a long time in our own country and the binding is neat and adequate. This work and Professor de Souza Araújo's *História* will amply furnish all that anyone need know of leprosy.

II Harold Scott

AGRICOLA, Ernani. Director do Serviço Nacional de Lepra. Campanha nacional contra a lepra. Nacional Campaign against Leprosy. Palestra proferida ao microfone da PRA do Serviço de Radiodifusão Educativa do Ministério da Educação e Saúde 7 de 1944 a 16 de 1945. 181 pp. 1944. Rio de Janeiro. Serviço Nacional de Lepra.

During the nine months—November 1944 and August 1945—Dr. Ernani Agrícola was directed by the Ministry of Education and Health of Brazil to deliver broadcast, almost every week, telling the people about leprosy and what was being done to deal with it in their own country. Thinking that these talks might be interesting and useful to a wider circle, the author has now collected them together and revised them in a small book. From the point of view of the man in the street inclusion, in this term, the intelligent layman, these broadcasts would doubtless accomplish what they purport to do, for they are expressed in simple, straightforward language, avoiding the use of technical terms.

They tell a little of the history of the disease in Brazil [among the authorities and authors mentioned we have failed to find the name of Professor de Souza-Araujo, probably the greatest authority in Brazil on this disease], and the following points are taken and spoken of in turn. Remarks on the epidemiology of leprosy and parallels between Brazil and other countries, such as India, Japan and the Philippines, the numbers of the afflicted, the numbers in special establishments and the types of these establishments, agricultural, asylums and hospital colonies. Several of these are referred to from time to time and the costs of their upkeep. Reasons are given for isolation and segregation and reference is made to various committees and societies for the relief of patients and their families, also to the methods for dealing with the children, for finding out concealed cases, for careful vigilance of patients to be discharged or kept under observation, for education of the people, propaganda and distribution of literature.

The broadcasts seem admirably adapted to their original purpose but, naturally, the detailed information is only of local interest and would not appeal in places outside Brazil.

H Harold Scott

DE SOUZA CAMPOS Nelson & BECHELLI, Luiz Marino. *Sintomatologia nervosa da lepra* [Symptomatology of the Nervous System in Leprosy] 193 pp., numerous figs on pls. Ministerio da Educação e Saúde, Departamento Nacional de Saúde, Serviço Nacional de Lepra. 1946. Rio de Janeiro. Imprensa Nacional.

This is another of the series of excellent monographs dealing with different aspects of leprosy and issued by the Leprosy Section of the National Health Service of Brazil. This one deals with the nervous manifestations, the tests therefor and the general and differential diagnosis.

The thesis is divided into two main parts. In Part I are described and discussed in sequence the sensory changes, the motor disturbances and the trophic and vasomotor symptoms. In Part II, the clinical tests, the examination of patients, the actual condition and evolution of the nervous manifestations, the differential diagnosis and a summary or epitome of the neurological lesions and their classification. Apart from numerous footnotes in the text, there is appended a bibliography of more than 150 references. The statements made, it will be seen, are well documented. There are very clear diagrams shaded to show the distribution of lesions in certain patients and other very detailed, but clearly reproduced figures to indicate the innervation of the muscles of the body and the roots from which the peripheral nerves arise, and another similar diagram of the cutaneous nerve supply. Photomicrographs demonstrate the histopathology of biopsy specimens of nerves and skin and, lastly, there are 59 photographs direct and X-ray to show the deformities and mutilations of the hands and feet and the bony changes produced by this disease.

To return to the letterpress. The methods of testing for the nervous symptoms are first detailed, the distribution of the anesthesia and paraesthesias. This section is followed by a description of the motor disturbances in arms, legs and face and thus by a consideration of trophic changes in skin, subcutaneous tissues, muscles and bones and the mutilations resulting from absorption, dry gangrene and ulceration. In Part II the clinical and laboratory examinations are discussed in greater detail, the histamine, pilocarpine and pricking tests and the methods of carrying them out. Laboratory tests include examination for bacteria, the Mitsuda reaction and biopsy. Succeeding this chapter on methods comes a section on the various clinical signs and symptoms, the

GUJIA MORALES E. (Catedrático de medicina legal Médico-director del Hospital Psiquiátrico Provincial de Cádiz) *Psicosis palúdicas y atebínicas. Trastornos psíquicos en el paludismo espontáneo, en el terapéutico y en los tratamientos con preparados atebínicos.* [Psychic Disturbances in Malaria: Spontaneous and Therapeutic, and in Treatment with Preparations Atebrin.] pp. ix+173 3 charts. Colección de Monografía de Investigación Médica. 1945 Barcelona J. M. Masó.

This is one of a series of medical monographs by Spanish authors of reputation, edited by J. M. Masó of Barcelona. In the present instance the author's first idea was to deal with the last only of the matters mentioned in the title, as he had seen several cases among patients treated with atebin (mepracrine), but later it was deemed advisable to enlarge the scope to include similar disturbances occurring in ordinary untreated malaria subjects and in patients undergoing therapeutic malaria treatment.

The study was begun in Cáceres where malaria is endemic, and continued in Cádiz. Before undertaking a description of malarial psychoses the author thought it would be wise to give a brief account of common psychoses which he designates "symptomatic psychoses" apart from the malarial form. The whole work is therefore divided into four chapters: 1. Symptomatic psychoses as met with in everyday clinical psychiatry. 2. Psychic disturbances in malaria "spontaneous malaria" as the author calls it. 3. Psychic disturbances occurring in patients undergoing therapeutic malarial treatment. 4. Psychic disturbances among patients treated by atebin preparations.

In chapter I he gives a brief account of psychic disorders which he subdivides into two main groups: those primarily cerebral or organic and those with functional toxic effects on the central nervous system. Under the latter are included disorders due to poisons *ab extra* as alcohol, morphine and lead and those occasioned by disease such as infections, endocrine disturbances, etc. It is to the latter that the author restricts the term symptomatic psychoses [Not a very satisfying classification, because "organic" causes will interfere with normal function, and, on the other hand, toxic effects may not be purely functional but may lead to definite lesion. In this connection the author refers to such conditions as hebeticity, mental confusion, anxiety, outburst of anger and of threat, of delirium, incoherence, mental perplexity, stupor, depression and hallucinations: after the fever has subsided there may be post febrile psychoses as emotional upsets, irritability, emotional hyperaesthesia, depression and hypochondria, impairment, perhaps loss, of memory.]

The malarial psychoses, chapter II, come to the notice of clinicians and malarialogists more often than that of psychiatrists. They are usually abrupt in onset and are seen as confusional states, patchy forgetfulness, exhaustion, hallucination, perhaps coma, or sudden mania, melancholia, hysteria's symptom: these usually accompany the febrile stage. In chronic malaria we see cases of depression and melancholia or apathy and indifference. Paranoia is not uncommon, especially, as is the author in tropical countries. It is not easy to differentiate organic malarial encephalopathy from psychoses not due to actual cerebral lesion. Perhaps there is no real distinction and the latter—extra-nervous psychoses—may be associated with cerebral lesion, not yet discovered. The symptoms may be due to vascular embolism or thrombosis, to punctiform haemorrhages with sudden loss of consciousness and, especially in children, with convulsions. Other conditions have been reported such as monoplegia, trismus, Parkinsonism, chorea, amnesia, epileptic attack and bulbar symptoms.

The author concludes that he can distinguish 7 clinical types: 1. That caused by malarial encephalopathy. 2. Symptomatic malarial psychoses due to the

physical action of the infection on the central nervous system 3 Symptomatic malarial psychosis proper 4 Endogenous psychosis in the course of a malarial attack 5 Abnormal psychic reaction provoked by the infection 6 Psychic symptoms attributed to malaria, but feigned by the patient as an interested person 7 Psychic disturbances of a non-malarial nature, but coinciding with a malarial infection [To the reviewer these seem somewhat artificial and not easily differentiated, with exception of type 6]

Therapeutic malaria, chapter III, has afforded an opportunity for observing certain types of psychosis produced by the action of malaria on different personalities, in particular general paralytics These cannot be ascribed solely to the malaria because some of them at least may be observed in patients with general paralysis treated with other pyrogenics, or even drugs such as neosalvarsan The following are specially referred to in this chapter

1 Paranoias with hallucinations (the so-called Gerstmann psychosis), or the schizophrenic The hallucinations are most commonly auditory, next visual or tactile, more rarely of taste or smell They are seen oftenest in the last days of the induced fever, or after treatment of the malaria, and it may be some time after Records show that 5-18 per cent of patients exhibit this form The case is quoted of a man of 45 years who at each access of fever became very excited, attempted to tear his clothes and to hurl himself through the window, would break every thermometer he used and, in the apyretic intervals, had auditory and visual hallucinations Under treatment by quinine the psychosis disappeared ten days after the temperature became normal

2 Suicidal tendencies The author differentiates those who attempt, and even commit, suicide owing to depression from their disease, before, during, or after treatment by malaria, and those who do so in the stage of depression after the course of malaria

3 Cases in which the patient does not react in the usual way to the malarial infection One case is recorded where the patient developed fever of a typhoid character after inoculation with the subtertian parasite and died in 10 days, in another patient general depression, a rapid pulse, diarrhoea and uraemic symptoms necessitated stopping the treatment at the third access of fever

4 Decline of the general paralysis symptoms, reversible or not, with psychosis One patient after the 6th access of fever stayed motionless, neither speaking nor appearing to understand anything, with uncontrolled sphincters, he had to be fed by tube The treatment was stopped at the 10th access of fever Six days later he had troublesome visual hallucinations, on the 10th he regained control of his sphincters, but convalescence was prolonged for two months

5 Epilepsy following malarial therapy

Chapter IV quotes reports of many cases of psychosis in the course of treatment of malaria by atabrin and repeats Kingsbury's explanation that the atabrin, by destroying the parasites more rapidly than does quinine, liberates a flood of toxin which causes the symptoms, or the atabrin has a direct toxic effect on the central nervous system

The author sent a questionnaire to the doctors of Cáceres and Cadiz, asking them how many malaria patients they had had in the preceding five years, how many had been treated with atabrin (or atepé), in how many of these they had observed psychic symptoms, and to give details He then quotes cases one with a manic-depressive state, another with sudden delirium, incoherence and insomnia (but several members of this man's family—uncle, father and sister—exhibited symptomatic psychosis), another had vomiting

and diarrhoea and complained that she was being poisoned and her food was bad, and at other times appeared perplexed and constantly asked what was happening. These symptoms did not occur when quinine was given, but only after atabrin. Other similar cases are noted.

The author then made some experiments administering atabrin to both persons to see if psychoses were set up in any of them. He gave each 5-8 tablets of atabrin (or atepel) daily for a week but though signs of intolerance such as vomiting might be seen none showed any psychosis. He then gave the drug intramuscularly the contents of an ampoule of 0.3 gm. of the hydrochloride. One subject on the fourth day became confused, kept looking under his bed to see if anyone was hiding there and on leaving his room seemed unable to recognise it on his return and went into others or he would remain motionless and mute or repeatedly say "Pardon me pardon me" say it again. This condition persisted for 16 days. The author concludes that atabrin can cause psychosis in man. This however was the only one among several who received the atabrin inoculation and the inference is drawn that there must be some susceptibility or tendency to psychosis also playing a part.

Analysing 34 cases the author finds that as regards

1. *Sex*—Nineteen were males, 15 were females—a difference of no moment.
2. *Age*—Twenty-one were between 9 and 43 years (years of puberty and adolescence) two only between 41 and 49 years. 8 were in the 51st decade and there was only one over 59 years (this totals 32).

3. *Others in family*—Eighteen gave a history of "psychic pathology" in close relations parents, uncles, cousins.

4. *Dosage of atabrin* which preceded the psychosis. Thirteen had the usual dose of 3.7 (3 tablets daily for 7 days). 13 others had less than this, 2.1 to 3.0. 7 had higher doses from 13.1 to 37.5.

5. *Stage of treatment when the psychosis was observed*—Thirteen showed symptoms during the course while in 20 the course was completed, or they were given a larger dose. In 11 of the 13 symptoms appeared after the ordinary dose of 3.7 with an interval up to 49 hours. In the other two the interval was longer 9 and 18 days.

6. *Course and termination of atabrin psychosis*—The commonest early symptom was mania with confusion and when this is all the prognosis is good, as the symptoms clear in a few days except for some restlessness and insomnia. Those with other complications clear up more slowly but all the other patients recovered in time without any residual psychotic change. In four only were the symptoms prolonged over a month in 27 there lasted from a few hours to one month.

Summing up the author states that atabrin psychosis occurs in 5 per thousand cases. In making a diagnosis it is far from easy to exclude endogenous psychosis and abnormal psychic reaction. With psychosis in untreated malaria we find parasites in the blood, whereas in atabrin psychosis we should not. On the other hand this is not all for a malarial psychosis may persist after the infection has been eradicated.

The subject bristles with difficulties and the distinction between ordinary psychoses and those due to malaria or to atabrin is not so easy in practice as it may be made to appear on paper. The author is however to be congratulated on the accomplishment of a difficult task and on having provided a basis for future work on a vexed question. See also FINDLAY *ibid* Bull. 1947 v. 44 703.

SUMMARY OF RECENT ABSTRACTS*

VII HELMINTHIASIS

TREMATODES

Schistosomes General

Distribution—DE MEILLON (p 190) discusses the general subject of schistosomiasis in the Union of South Africa. *S. haematobium* has been there for many years, but *S. mansoni* was introduced recently from the north, and is spreading. He gives a list of the snail hosts of these worms, and makes the point that if the rivers of South Africa are dammed for industrial purposes they will become suitable for the breeding of snails. The immigration and settlement of large numbers of people from neighbouring countries, many of whom are infected, will tend to spread the disease unless adequate measures are taken to prevent it.

WILKINS (p 443) writes of schistosomiasis in S Rhodesia, where in Africans infection rates of 30 per cent for *S. haematobium* and 8 per cent for *S. mansoni* were found after a single examination of many thousands of specimens. He thinks that so many people are infected that treatment alone cannot cope with the situation, and he describes the methods he has found useful for killing snails in quiet rivers, ditches and canals, by means of copper sulphate. In comment, ALVES points out that the method can hardly be applied to rivers with broken and irregular banks. GELFAND (p 796) refers to the very heavy rates of infection found in the Africans of Mashonaland, and to the late sequelae and complications of schistosomiasis. Details should be sought in the original.

Schistosomiasis is common in Nyasaland and *S. haematobium* eggs were found by RANSFORD (p 618) in 50–80 per cent of urines of those in Kota Kota hospital or living on the lake shore, *S. mansoni* eggs were found in about 1 per cent of specimens of faeces, a reduction from the 7 per cent of 10 years earlier. The only snail found infected was *Physopsis globosa*. The author discusses the habitat of this snail, and the use of drainage, and of *Tephrosia vogelii*, in controlling the snail host.

LOVETT-CAMPBELL (p 793) shows that *S. haematobium*, and to a smaller extent *S. mansoni*, were common in West African troops during the war, and that infected soldiers soon broke down under prolonged stress.

*The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1948 v 45. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.

SCHWITZ (p. 348) has written a monograph on the classification and nomenclature of the Planorbidae especially of the Belgian Congo. This is a very difficult family, and the author advises that specimens taken in the field should be submitted to leading malacologists for identification.

CONYER (p. 444) makes the point that species of snails which serve as intermediate hosts of schistosomes in certain areas may be susceptible to the same species of schistosomes in other countries. He gives examples, and concludes that this species-specificity or even strain-specificity is important in any species sanitation of snails.

WRIGHT (p. 913) has summed up the geographical distribution and snail hosts of *S. haematobium*, *S. mansoni* and *S. japonicum*.

KERYXAS (p. 445) shows that *Physopsis africana* is the common host of *S. haematobium* in part of the French Sudan, and that it is also found infected with *S. mansoni*, but much more rarely. *Planorbis aduncus* is commonly a host of *S. mansoni* in the same area. He discusses other fresh-water snails investigated.

Hosts.—BOSCARDI (p. 87) has studied the development of *S. haematobium* in the host snails. He shows that the miracidia do not penetrate the skin, but enter by the mouth. He claims that only one miracidium develops in a snail, some sort of immunity seems to prevent invasion by a second miracidium. MALDONADO and ACOSTA MATEO (p. 187) on the other hand give a different account of the process of infection of *Australorbis glabratus* by miracidia of *S. mansoni*. They state that the miracidium penetrates the epidermis and that a snail may be parasitized by numerous miracidia, though not all of these will develop. The authors describe in detail the successive stages of the developing embryo in the tissues of the snail. FOX BRANT and FILLS (p. 376) have found that infection with *S. mansoni* interferes to some extent with the metabolism of *Australorbis glabratus*, but have not decided whether this effect is due to toxic action of the parasite.

HENYER *et al.* (p. 349) found that in various batches of *Oreochromis murrilli* the best results were obtained when each snail was exposed to 5-10 miracidia of *S. japonicum* (compare Boscardi above). A period of about 11 weeks is required for the development of cercariae.

Schistosomes.—CRAX *et al.* (pp. 914-915) discuss the infection of laboratory animals with the human schistosomes and VOLLERS *et al.* (p. 349) have described a perfusion technique for recovery of schistosomes from laboratory animals.

JARVIS (p. 617) has made a contribution in which he discusses the nomenclature of the genus sometimes named *Schistosoma* and sometimes *Bilharzia*. The matter has been referred to the International Commission on Zoological Nomenclature but a ruling has not yet been given.

The survival times of cercariae of *S. japonicum* and *S. mansoni* in water at various temperatures and pH values were investigated by JONES and BRADY (p. 916). Survival was possible for 8 days at 5°C. but for only one minute at 35°C. Slight acidity or alkalinity made no difference. Water treatment processes were investigated by the same authors (p. 918) for their effects on cercariae of *S. japonicum* and *S. mansoni*. Coagulation was not useful, but filtration through Swiss pad held back the cercariae completely. Certain chlorine compounds showed good effect and also two iodine compounds provided that not too much organic material was present. Certain other chemicals were also effective.

Miracidia of *S. japonicum* and *S. mansoni* are killed within 30 minutes of chlorination or chloramination to total residuals of 0.1 to 0.4 p.p.m. JONES and HENYER (p. 919) show that eggs are more resistant and are killed in 30 minutes only at total residuals of 3.9 to 11 p.p.m. though longer exposure at lower residual may be effective.

In a comprehensive investigation of the effect of sewage treatment processes on the eggs of *S. japonicum* JONES *et al* (p 917) have shown that sedimentation removes most of the eggs within 2 hours, but that anaerobic sludge digestion, sludge drying, and trickling-filter treatment were not very successful in destroying eggs. Activated sludge is a good medium for the hatching of eggs. Intermittent sand filtration, with sand of a certain size is an efficient method of removing the eggs from treated sewage.

Clinical findings—MERRIFER *et al* (p 794) in *S. Rhodesia* have found that rectal biopsy is much more satisfactory than Weller's scraping method for diagnosis of rectal schistosomiasis though the latter is of considerable value in Egypt and the Caribbean, where infections are heavy. The intradermal test with the authors' cercarial antigen gave more positive results than rectal biopsy. In *S. Rhodesia* rectal infection with *S. haematobium* is quite common.

ELIAS and TALAAT (p 715) have found liver biopsy a simple, safe and useful means of diagnosing hepatic schistosomiasis: they found eggs of *S. haematobium* or *S. mansoni* in 21 of 41 specimens from cases examined in Egypt.

LAIST (p 710) has contributed a detailed discussion of the ectopic lesions found in schistosomiasis, which are those produced outside the portal-caval venous blood channels. In 82 cases, 21 were attributable to *S. haematobium*, 12 to *S. mansoni* and 49 to *S. japonicum*: most of those due to *S. haematobium* were outside the brain but most of those due to *S. japonicum* were within it. The ectopic lesions can usually be accounted for by the natural valveless intercommunicating channel between the portal and caval veins. The lesions may develop several years after intestinal or vesical lesions have disappeared.

REUTER and KRUM (p 448) describe a case of infection with *S. japonicum* in which there was a granulomatous tumour of the brain which contained many *S. japonicum* eggs. The tumour was removed and the patient made a good recovery after the operation and after treatment with antimonials. HEST *et al* (p 624) report a case of cerebral schistosomiasis in which the signs were those of cerebral tumour. A nodule which contained eggs of *S. japonicum* was removed from the brain and under antimony treatment the patient made a good recovery.

KATZ (p 1017) reports a case in which eggs of *S. mansoni* were found in a brain thrombus and another in which they were present in a mass of fibrous tissue in the spinal canal compressing the cord.

ATTE (p 718) has written a book on biliary cancer but he points out that there is little or no evidence that the schistosomes are specific causes of cancer. He discusses diagnosis and treatment of cancer associated with schistosomiasis. MAKAI REY (p 795) reports two cases of biliary papilloma and epithelioma.

LOWMEYER *et al* (p 716) have investigated the educational attainment of European and African children suffering from schistosomiasis. They found no evidence that the disease had an adverse effect in European children but the few non-schistosome-infected African children. They discuss the implications of these findings.

best given by mouth and HAWKING and ROSS (p. 796) found that a dose of 0.2 gm. repeated daily was tolerated. They studied blood levels and tissue concentrations and the effects of overdosage in animals. HALAWANI *et al.* (p. 771) have studied the blood levels of Miracil D after oral administration and recommend that it should be given at intervals of 12 hours. WATNEY *et al.* (p. 1018) have used Miracil D in *S. haematobium* and *S. mansoni* infections in Egypt. It is given by the mouth and toxic effects are slight. It is effective against both worms, but with the doses used, complete cure is not usually obtained. In comment HAWKING refers to the better results he and his colleagues obtained, with higher doses, in S. Rhodesia. HALAWANI *et al.* (p. 77) have used Miracil D in patients infected with *S. haematobium* and they conclude that the effective dose is not less than 18-20 mgm. per kgm. daily for 7-8 days the blood concentration must reach 0.5 mgm. per 100 ml.

LIPPINCOTT *et al.* (p. 527) have studied the distribution and fate of antimony in the body after administration to patients with *S. japonicum* infection. Details should be sought in the original. In tests of white rats after administration of radio-active tartar emetic NESS *et al.* (p. 447) noted anomalies in distribution of antimony in the blood and tissues, and suggest that if rats are used to screen antimonial compounds such findings should be interpreted with caution.

GIRGIS and AZIZ (p. 446) have used an intensive 2-day course of injections of sodium antimony tartrate in the treatment of schistosomiasis in Egypt, and although they report fairly good results they incline to think this method too drastic for large-scale campaigns. TALANT and SHOUH (p. 719) have tried various intensive courses of treatment for schistosomiasis in Egypt and finally recommend two injections of tartar emetic at intervals of 6 hours, on two consecutive days (a total of 8 grains of the drug). In comment ALVES points out that certain details are not made clear by the authors.

The question of acquired tolerance to tartar emetic and some other antimonials has been studied by PAX (p. 86). Trivalent and pentavalent antimonials produce tolerance and are not cumulative: the toxicity of tartar emetic is increased if the experimental animals are starved.

As a result of experimental work on monkeys infected with *S. haematobium* SAID EL AYADI (p. 720) concludes that Repodral (Fouadim) is curative if given by the mouth together with riboflavin.

ROSS (p. 619) reports very poor results from the use of acriflavine in the treatment of schistosomiasis.

S. haematobium

GARD and MAURICE (p. 912) confirm the existence of urinary schistosomiasis in the Wady Sous region of Morocco, but GARD *et al.* (p. 1015) give evidence that infestation with *S. haematobium* has declined recently in Morocco as a whole.

BOIRON and KÖRBER (p. 93) name the endemic areas of *S. haematobium* infection in French West African territories. These are very extensive the disease being found along the main water-routes. The incidence is probably some 15-20 per cent. in schoolboys and local troops.

GORMAN *et al.* (p. 239) describe a method for hatching out the eggs of *S. haematobium* and detecting the presence of the miracidia released. It is often important to know if viable eggs are present in urine.

BLAIR and ROSS (p. 1094) describe the antigen they prepare from cercariae emitted by *Physopsis africana* infected in nature: these cercariae may not all be *S. haematobium* but no claim has ever been made that antigens from cercariae are species-specific. They have followed the course of the reaction after

intradermal injection of this antigen in infected persons, and show that it differs markedly from the course in uninfected persons. The optimum time for reading the tests is 15 minutes after the injection.

GELFAND (p 913) shows that the ureters are often affected in vesical schistosomiasis in *S. Rhodesia*, he has found ova in the submucosa and the muscular layers, and notes that the pathological changes lead to dilatation, but he has not seen true stenosis.

TALAAT (p 1093) argues that kidney function is impaired in urinary schistosomiasis and that tartar emetic treatment does not impair the function in the doses normally used.

In the hands of BLAIR *et al* (p 526) Miracid D gave poor results in the treatment of *S. haematobium* infections in *S. Rhodesia*, but later results were better, see Hawking above.

KIESER (p 526) comments on the deleterious effect of *S. haematobium* infection on the intelligence and vigour of children in South Africa.

In discussing the control of *S. haematobium* infection in Algeria, MARILL (p 798) makes the point that the disease is largely associated with the irrigation systems, and that although it is not possible to deal with all the large number of snail foci in the country, those in the irrigation canals can be controlled. Engineers should know that snail elimination is an essential part of their work. Canals should be cemented and dried periodically, and copper salts can be used for the parts of the irrigation system which are permanently under water. Similar measures are also useful in malaria control. BLAIR (p 1095) discusses the public health aspects of schistosomiasis in *S. Rhodesia*, where, he thinks, both the urinary and the intestinal forms are spreading. Attack on the worm can be pushed by intensive treatment, and on the snail by the use of copper sulphate and by the planning of irrigation works and water-storage dams with schistosomiasis in mind from the beginning. He makes the point that cercariae can live 100 hours in winter.

KHALIL and HALAWANI (p 527) do not consider that the preparation known as Cloroben is suitable for use against snails, because it is lethal to fish and rice plants.

S. mansoni

SCHWETZ and DARTEVELLE (p 348) have published a detailed study of intestinal schistosomiasis in the Kasenyi area of the Belgian Congo, in which they show that it is not particularly associated with fishing. The monograph is chiefly concerned with a malacological survey of the area from Lake Kivu to Lake Albert, and a description of the species found. SCHWETZ (p 1015) has contributed a long paper on schistosomiasis in the Lubilash area of the Belgian Congo, where the incidence of *S. mansoni* is up to 14 per cent (50 in one district). It is a disease of cultivators, and may be concerned in some cases of the condition known as *disboba*. He gives a list of the snail vectors.

HEISCH (p 671) reports infection with *S. mansoni* in 11 per cent of a group of Africans near Taveta, Kenya.

S. mansoni infection is endemic in several places in Eritrea, and FERRO-LUZZI (p 1017) has found that *Planorbis abyssinicus* and *P. ruppellii* are hosts.

LUTTERMOSER (p 447) has contributed a comprehensive account of schistosomiasis in Venezuela where there are probably more than 50 000 cases along the coast and the main drainage systems. The snail host is *Australorbis glabratus* and the author describes the methods used to eradicate it by drainage and the use of copper salts or lime. There is a special risk in connexion with the cultivation of water-cress, sugar-cane and a certain reed which is used for animal packs.

MIRAS (p. 346) has written a long monograph on schistosomiasis in Brazil where it has been estimated that some 3 000 000 people are infected. He thinks that this is probably an under-estimate. In some places the infection rate (on the evidence of examination of faeces) is as high as 56 per cent. in the age group 11-15 years. The snail hosts are *Australorbis glabratus* *Planorbis guadeloupensis* and *P. dilatatus*. [Some authorities regard *A. glabratus* as the correct name for *P. guadeloupensis*.] PORTELA (p. 347) gives an even higher figure for infection in Pedra Azul, Brazil, where he found it in 83 per cent. of 1,500 persons of all ages over 2 years. JANSEN (p. 85) shows that infection with *S. mansoni* in part of Pernambuco, Brazil, is present in 6.6 per cent. of children up to 4 years of age, not 40 as in the abstract] and that the proportion rises to 71 per cent. at age 15-24 falling to 33.4 per cent. over 35 years. The snail concerned is *Australorbis cent. metrahi*. In treatment tartar emetic gave the best results, but other antimonial salts were also useful. In a survey conducted along the Victoria Minas railway in Brazil BASTRES and PACTOJA (p. 191) found infection with *S. mansoni* in 71 per cent. of the people living near the river Doce, but in only 0.9 per cent. in communities far from that river. Infection of snails (*Planorbis dilatatus*) found in various collections of water showed a singular trend to infection in man. DE MAGALHÃES and ROCHA (p. 618) report on the increasing incidence of *S. mansoni* infection in Mina Gerais, Brazil. In some towns the rate in school children of infection is over 60 per cent.

MONTESIEUX *et al.* (p. 259) show that *S. mansoni* is an important cause of dysentery in Martinique where *Planorbis guadeloupensis* [see comment above] is the snail host.

ELSDON DEW (p. 188) has used the zinc sulphate flotation method of Faust for detecting worm eggs in faeces but though this is useful for hookworm eggs it is not so good for schistosome eggs, which do not float well.

OTTOLINA (p. 915) writes of the value of rectal biopsy in diagnosis of *S. mansoni* infections, by which means many cases negative to stool examination are found to be positive. He (p. 183) shows that if the fragments of tissue obtained by rectal biopsy are immersed in fresh water for a few minutes they become sufficiently transparent to allow schistosome eggs to be seen under the microscope. In this way a diagnosis may be made within a very short time. DA SILVA and COSTA (p. 194) also write of the value of rectal biopsy in simplifying the diagnosis of *S. mansoni* infections.

MARTINEZ VILLAFRANCA and LANC (p. 1085) have used Neostibosan for *S. mansoni* infections but without much success.

DA SILVA (p. 85) describes his tests of Stilboplex III, a compound of antimony and iodine which he has used with some success in the treatment of *S. mansoni* infections of animals and in four human cases. The drug is given intravenously at intervals of 1-3 days to a total of 10-15 injections.

NOVA BRUNTEZ (p. 619) writes of the value of splenectomy in hepatic cirrhosis which is a result of *S. mansoni* infection. The operation may relieve portal hypertension if performed before the liver damage is excessive. He gives details of 20 cases in which he removed the spleen for this condition.

VIGLI (p. 83) has investigated hermaphroditism in *S. mansoni* and notes that male worms which also possess ovaries tend especially to develop in animals which are not optimum hosts (guinea pigs and rabbits) but not in man and monkey. The development of these hermaphrodite males is also stimulated by the absence of a female partner as in animals infected by male worms only. He discusses the implications of these findings.

CRAM *et al.* (p. 914) has shown that the North American snail *Trojanella* *arctica* can act as host for *S. mansoni*.

S japonicum

WRIGHT *et al* (p 194) report a survey carried out in Japan. They used a simple sedimentation technique for the examination of faeces, and found infection in 22.6 per cent of 1,688 school children. More boys than girls were infected, and the rates varied in different places, up to 53.5 per cent in one. These results are much higher than those reported by the Japanese, and this is probably due to the more efficient examination carried out by the present authors than the single faecal smear used by the Japanese. The snail host is *Oncomelania nosophora*, and infection was found in various collections of these snails, up to 15.8 per cent in one place.

PESIGAN (p 622) reports a new focus of schistosomiasis in Luzon, Philippine Islands, the snail *Oncomelania quadrasi* was also found.

ABBOTT (p 1096) has written a handbook on the medically important molluscs of the Far East, with instructions for identification in the field. He cites five hosts of *S japonicum*—*Oncomelania quadrasi*, *O formosana*, *C nosophora*, *O nosophora slateri* and *O lupensis*.

WARD *et al* (p 915) describe their methods of maintaining snails in the laboratory, they exposed certain American snails to *S japonicum*, but only *Pomatiopsis lapidaria* showed signs of infection, and these were regarded as inconclusive. ABBOTT (p 1097) describes *Pomatiopsis lapidaria* in detail.

BRACKEN *et al* (p 1098) describe the lesions of acute *S japonicum* infection in man, their findings having been made in men killed in the war in the Philippines. The appearances are very similar to those seen in experimental animals.

HUNTER *et al* (p 623) report on trials of 10 techniques for recovering eggs of *S japonicum* from faeces. They recommend two methods which involve the use of HCl, sodium sulphate, Triton NE and ether, with centrifugation at different stages, but for details the original should be consulted. JAHNES and HODGES (p 623) use 10 per cent ethyl alcohol (sp gr 0.986) for emulsifying faeces and sedimenting eggs of *S japonicum*, with success.

Although they detected some value in intradermal tests or complement-fixation tests with antigens from adult *S mansoni* or (especially) from their cercariae, in *S japonicum* infections, BOZICEVICH and HOYEM (p 916) did not think that they were as useful as examination of faeces.

VOGEL and MINNING (p 196) have studied the effects, on adults and eggs of *S japonicum*, of tartar emetic, Fouadin and emetine injected into animals infected with that worm. These are described in detail. The first two drugs could effect cure if doses were given 15–18 times, but no cures were obtained with emetine in this series. CARROLL and HUNNINEN (p 624) treated a series of American soldiers who were infected with *S japonicum*, by intravenous injections of tartar emetic given every other day. The results were slightly better than with Fouadin.

In a test of a large number of compounds, to find those which would protect against cercariae of *S japonicum* after clothing had been impregnated with them, WRIGHT *et al* (p 527) found that an emulsion of 4.5 per cent benzyl benzoate with 0.5 per cent Tween 80 in water was the most effective. Garments impregnated with this and then dried, protect even after having been washed four times. Dibutyl phthalate emulsion is also useful, and so is a secret gas protective chemical. The type of cloth impregnated is important, wool being better than cotton or twill. The same authors (p 529) investigated the protective effects of repellents and repellent ointments for application to the skin. Many showed useful effect, but tests are needed to determine the length of time during which these would remain effective on continuous exposure to water. These experiments were conducted during the war. Similar investigations are reported by NOLAN *et al* (p 919), who found that dibutyl phthalate

CALLOT J. Le paludisme en Alsace et en Moselle. A propos d'une enquête récente. [Recent Inquiry on Malaria in Alsace and in Moselle.] *Ann. Parasit. Humaine et Comparée* 1948, v 23 Nos. 5 & 290-95 3 maps.

Alsace was one of the most malarious regions of France in the last century. Even Strasbourg was affected. The endemic had completely disappeared however by 1893. Inquiries carried out by order of the German government after the annexation of Alsace in 1871 determined the geographical distribution of the disease. The findings as concerns Lower Alsace are recorded on a map. Foci of infection were found along the Rhine including Strasbourg and its environs in the marshland bordering the River Ill along the River Bruche and along the Marne-Rhine Canal.

Malaria was also endemic in Moselle until the middle of the last century notably in the Sarre Valley.

None of the explanations that have been advanced account satisfactorily for the disappearance of malaria about 1893 from both Alsace and Lorraine. The regularization of the course of the Rhine cannot account for it. Stabling cattle in Alsace was practised long before the disappearance of malaria. This practice may well have encouraged the deviation of *A. maculipennis* from man to cattle. *A. m. rusticus* is now the predominant species. In Lorraine cattle are not kept in stables.

A certain amount of anxiety was occasioned by the possibility that the introduction of a large number of infected persons into this area during and after the last war might reactivate these old foci of infection. Anophelines are still numerous. The author addressed an inquiry to all medical practitioners in these areas regarding the occurrence of locally acquired malaria infections. From this inquiry it was learnt that though imported cases of malaria had been widely scattered throughout the area being reported from more than 50 localities in the Lower Rhine area, only two indigenous infections over and above the few that have been published, had been observed. In these cases races of *Anopheles* theoretically capable were responsible for transmission. It would appear that the persistence of anophelism in France need occasion no undue anxiety.

HORMANN H. Malaria in Deutschland 1945 bis 1947. [Malaria in Germany 1945 to 1947.] *Zeitschr. f. Tropenmed. u. Parasit.* Stuttgart. 1949 v 1 No. 1 32-91 77 figs. [Numerous refs.]

This paper deals with the spread of malaria in Germany as the aftermath of war. The question arises whether this may be due to the increase of the endemic area owing to the deterioration of hygiene or whether it was due to importation of fresh cases. The incidence of malaria in Germany in the period 1945-1947 is important for the present purpose. No less than 13,826 cases of malaria were notified, and of these 3,581 were indigenous. These figures must be regarded as minimal because in the post-war period public notification became disorganised and this had distinct influence on hygiene. By far the greatest number of autochthonous cases were observed in 1946 (7,335) while the decline in 1947 (1,226) could be regarded not so much as the beginning of a definite diminution, but as result of unfavourable meteorological conditions for breeding the transmitting species of *A. gambiae*. The most heavily infected areas were the towns of Frankfurt, in Odes and Berlin also the districts of

Lebus and Bernau and the whole of Schleswig-Holstein—in these an increase of endemological distribution has taken place. A very important epidemiological consideration in this epizootic has been the existence of a reservoir of infection and the opportunities which have been afforded for its spread by the fluctuations and herding together of the population. But, apart from this, it is an entomological problem and depends upon the prevalence of *Anopheles* and especially upon the presence of appropriate races of *A. maculipennis*. Especially important is the influence of microclimate upon the distribution and predilection of *Anopheles* and their intimate human relationships.

In addition to the monthly increase of fresh infections the problem of periodic recurrences of clinical manifestations comes into play. The Dutch view that the northern European type of *Plasmodium vivax* recurs at yearly intervals and that, generally speaking, the incubation period may be prolonged to such an interval could not be confirmed in Germany.

SWAROOP, S. Forecasting of Epidemic Malaria in the Punjab, India. *Amer J Trop Med* 1949, Jan, v 29, No 1, 1-17, 4 charts

In 1921 the Punjab Government undertook the task of preparing annual forecasts of the probable extent of epidemic malaria, and after some preliminary work the forecasts assumed a standard form in 1923. They were at first prepared by GILL who himself devised the method based primarily on observations made by CHRISTOPHERS, but were later prepared by YACOB [see YACOB & SWAROOP, this *Bulletin*, 1945, v 42, 620]. They were based on a consideration of the rainfall, the spleen rate, the epidemic potential or co-efficient of variation of 'fever' mortality during the month of October since 1868, and the economic conditions represented by food prices.

On the partition of the Punjab, and hence the ending of these forecasts in their standard form, the author submits their results since 1923 to statistical analysis. He shows that they attained a high degree of general accuracy which has not varied materially in different periods or between the times when Gill and Yacob were responsible. There has been a steady decline in the trend of the annual epidemic figures from 1867 onwards, and epidemics appear to run in a cycle of eight years, though the author accepts this observation with caution. On statistical analysis of the utility of the factors on which forecasts are based, the author shows a previously unsuspected correlation between epidemic happenings and rainfall in the previous May (co-efficient of correlation 0.563) which should make earlier forecasts possible in future, and finds that contrary to Gill's opinions the spleen rate is not significant in forecasting so that its estimation may be omitted without loss of accuracy. [This is an excellent statistical analysis of a pioneer service. Though partition may alter the form of forecasts it would be very regrettable if they should be discontinued.]

MATTINGLY, P. F. Anopheline Pupae (Diptera, Culicidae) from West Africa. *Ann Trop Med & Parasit* 1949, Apr, v 43, No 1, 23-5, 2 figs

This paper contains descriptions of the pupae of *Anopheles rufipes* var. *ingrami* and *A. flavicosta* and indicates the position of the latter species in the identification key given by DE MEILLON [this *Bulletin*, 1948, v 45, 295].

H S Leeson

in this long series made up of a great variety of infections, congenital malaria was absent. It is suggested that possibly the extraordinary number of phagocytes in the placenta constitutes an obstacle to the trans-placental passage of the parasite. Malaria in the mother appeared to affect the health of the infant by causing a low weight (2,000-2,500 gm.) at birth. Deaths in the newly born were 6-8 per cent. during the first eight days but syphilis and other conditions were found to be the cause as well as malaria.

- i. MACKERRAS M. J. & ERCOLE, Q. V. Some Observations on the Action of Quinine, Atebrin, and Plasmoquine on *Plasmodium vivax*. *Trans. Roy. Soc. Trop. Med. & Hyg.* 1949 Mar v 42, No 5 443-54 3 graphs & 4 coloured figs. on 4 pls. [10 refs.]
- ii. — & — Observations on the Action of Quinine, Atebrin, and Plasmoquine on the Gametocytes of *Plasmodium falciparum*. *Ibid.* 455-60 7 graphs.

i. Many theories have been put forward to explain the mode of action of quinine and other drugs on malarial parasites. The *in vivo* studies by CHRISTOPHERS and FULTON (this *Bullet.* 1934 v 35 709) and of American authors subsequently up to the investigation of MORTIMER (ibid. 1949 v 48 445) have shown that the action is probably direct on the parasites. The present authors have recently described (this *Bullet.* 1948 v 43 306) the changes which occur in the sexual and asexual forms of human malaria during normal development in the peripheral blood and after treatment with paludrine. The present experiments carried out with Melanesian strains of *P. falciparum* transmitted by *Anopheles punctulatus punctulatus* to susceptible white hosts were made while the authors formed part of the Medical Research Unit at Cairns, Australia. The effect of quinine, atebrin (mepacrine) and plasmoquine (pamaquin) on the growth and development of the parasites in the patients' blood was observed by means of fresh preparations and stained films and in mosquitoes which were fed on the infected hosts during treatment. The appearance of parasites developing normally and those in contact with the drugs are shown in coloured plates. It appeared that quinine and atebrin acted similarly the latter more effectively on the erythrocytic stages of the parasite which metabolize haemoglobin evidenced by pigment production. Growth was affected and morphological changes were apparent after a few hours. Mature gametocytes were not affected, and developed normally in the mosquito. Plasmoquine had some effect on all stages of sexual growth and to some extent on gametocytes for no mosquito infections were obtained 42 hours after treatment started.

ii. In continuation of the experiment described above the effect of the same three drugs on the gametocytes of *P. falciparum* was studied. It was confirmed that therapeutic doses of quinine or atebrin did not influence the numbers morphology (except that atebrin sometimes gave rise to unpigmented

forms, as noted previously by SINTON [this *Bulletin*, 1939, v 36, 396]) or infectivity of mature forms to mosquitoes Quinine did, however, appear to affect young forms adversely, and numbers were ultimately reduced This effect of quinine is comparable to that noted by BLACK [this *Bulletin*, 1947, v 44, 176] in the case of trophozoites *in vitro* The marked effect of plasmoquine on gametocytes was also confirmed When mosquitoes were fed on patients three hours after treatment with 10 mgm of this substance infection still occurred, but its intensity was reduced after six hours, and notably so after nine hours At the end of 15 hours no gland infections were noted in spite of the presence of numerous sexual forms in the patient's blood up to 25 hours after treatment, when exflagellation still occurred Thereafter the gametocytes gradually degenerated and disappeared

WAR OFFICE Malaria Relapses treated with Quinine and Quinine Substitutes
Statistical Report on the Health of the Army 1943-1945 1948, 273-6,
 1 chart

In accordance with a directive sent to military hospitals in the United Kingdom all cases of malaria relapse were to be treated with one or other of the two following courses of treatment, without any further antimalarial maintenance treatment

Course I Mepacrine 0.2 gm, with a copious draught of fluid, every six hours for 48 hours, then 0.1 gm thrice daily after food for 10 days

Course II Quinine in solution ten grains and pamaquin 10 mgm, concurrently, thrice daily after food for 10 days Patients to remain in hospital throughout treatment, pamaquin to be discontinued if cyanosis or abdominal colic appear

Six hundred and fifty patients with *P. vivax* relapses were treated with Course I, 584 with Course II During a period of five months from the end of treatment the percentage of patients who relapsed after Course I was 34, after Course II, 10.3 Relapses after Course II occurred earlier (maximum in fifth week) than after Course I (maximum in eighth week)

The same superiority of Course II in preventing relapse was noted in the treatment of first attacks The relapse rate after the treatment of 100 such cases with Course I was 29 per cent, of 76 cases with Course II, 5 per cent (five months period)

A graph which is appended to the text illustrates the periodicity of *P. vivax* relapses with a major peak in the second and a minor peak in the ninth month

Norman White

WAR OFFICE B T Malaria Relapses treated with Paludrine *Statistical Report on the Health of the Army 1943-1945* 1948, 277

Male patients suffering from relapsing *P. vivax* malaria admitted to the Colchester Military Hospital were treated alternately with one of the three following methods of treatment —

A Quinine 10 grains and pamaquin 10 mgm thrice daily for 10 days

B Paludrine [proguanil] 25 mgm twice daily for 10 days

C Paludrine 250 mgm twice daily for 10 days

Every third patient received one and the same treatment, consecutive patients in order of reception received different treatments Follow-up was by written questionnaire Six months after the end of treatment the results were —

Course A 107 treated, 19.6 per cent had relapsed

Course B 108 treated, 54.4 per cent had relapsed

Course C 107 treated, 48.6 per cent had relapsed

The paludrine courses were much less effective in preventing relapse than quinine-pamaquin but it may be that more frequent administration of paludrine would give results as good as or better than those obtained with quinine-pamaquin.

COATNEY G. R. *Chemotherapy of Malaria. Bol. Oficina Sanitaria Panamericana* 1949 Jan. v 28, No. 1 27-37 4 figs. (4th rels.)

This is a succinct account of the newer antimalarials which should prove of value to those called upon to treat the various forms of the infection. Much of the co-ordinated search for new drugs of this type was carried out in the United States and to a lesser extent in Britain. In the U.S.A. more than 1400 compounds were tested against avian malarial infections and the pharmacology and toxicology of a proportion were studied in mammals. About 100 were tested in human patients. In view of the shortcomings of quinine SHANLEY and co-workers made an intensive physiological and antimalarial study of atebrom (mepacrine) and, in conjunction with the work of FAIRLEY the knowledge thus acquired allowed this substance to be used with remarkable success as a suppressant in the field. Chloroquine (SN 7818) a 4-aminoquinoline synthesized and tested by the Germans, is a limited extent, under the name resochin as early as 1934 ranks high as a therapeutic and suppressive agent. (For a description of its properties see this Bulletin 1946 v 45 708. HIKETH has recently stated that this substance was captured in North Africa in 1941 and taken to America where its constitution was discovered. The present account of its history differs somewhat.) It may be given intramuscularly to comatose patients and rapidly relieves acute attacks of the three human malarial. Other substances of value in the series are vantoquin (SN 8811) (a 3-methyl derivative of resochin also made by the Germans) oxychloroquine (SN 8317) and camoquin (SN 10751). Paludrine the chief British contribution to this field of research, is of outstanding value as a therapeutic and suppressive agent with a wide margin of safety. In practice the author does not consider it superior to chloroquine. Pentaquine (SN 13276) this Bulletin 1947 v 44 396 and isopentaquine (SN 13274) which are 8-aminoquinolines related to pamaquin (plasmoquine) appear to have definite advantages over the latter. When given along with quinine the relapse rate in benign tertian malaria was considerably lowered. Although less toxic than pamaquin these substances require to be given under medical supervision because of danger to the circulatory system and their routine use with quinine is not recommended.

Abstracts of papers on the chemotherapy of these substances have appeared in this Bulletin.

J. D. Fulton

HIKETH W. & MUDROW REICHENOW. *Lith. Neue Wege in der Chemotherapie der Malaria. New Developments in the Chemotherapy of Malaria. Dtsch. med. Woch.* 1949 Jan 28 4 v 4 97-101 29 refs.

This is a short review of progress in the chemotherapy of malaria dating from the discovery of plasmoquine and atebrom (mepacrine) to the present day. It has a hard luck ring about it. During the war when it was found that quinine in reasonable doses failed to act satisfactorily as a prophylactic or suppressant atebrom in daily doses 1.01 gm was found to be effective as a suppressant. Before the war a certain amount of doubt was expressed as to the value of atebrom in Britain and in Germany search was therefore made for a drug to replace it. Resochin and vantoquin were synthesized then the

the late war They bear a constitutional resemblance to atabrin, if one benzene ring and substituents be removed from the latter, resochin being 4-diethylaminoisopentylamino-7-chloroquinoline and sontochin its 3-methyl derivative Both resembled atabrin in properties, and were active against schizonts but had no causal prophylactic action They did not colour the skin and could be used with plasmoquine [pamaquin] without giving rise to untoward effects In 1943 sontochin was captured by the Allies in North Africa The whole series including resochin was discovered as a result of intensive work in America [see also COATNEY, above] The latter was named chloroquine (SN 7618), and its properties have been fully described [this *Bulletin*, 1946, v 43, 708] Resochin and sontochin were also tested by FAIRLEY at Cairns, Australia, during the late war Nivaquine C is the dihydrochloride of sontochin, other salts were given the names Nivaquine M or R, and were preferred by the French to atabrin Reference is also made to the discovery of paludrine, some space being devoted to the fact that resistance to it has been induced in *P. gallinaceum* but no reference is made to the fact that similar resistance to plasmoquine was readily induced in *P. knowlesi* The search for something to replace plasmoquine, which was toxic, led to the discovery of Certuna in Germany before the war and to pentaquine in the U.S.A. during the war, but neither has come into general use Although large numbers of new sulphonamides have been synthesized, all have proved disappointing in treatment of malaria Endochin, a 4-hydroxy-quinaldine tested by the author had marked prophylactic properties in bird malaria but was inactive in human and monkey malaria In a search for guidance in the synthesis of active substances in malaria later work has tried to elucidate the metabolic requirements of plasmodia and the mechanism of drug action It remains to be seen whether the more scientific approach will yield more fruitful results than the older method of trial and error

[All the investigations mentioned in this article have been abstracted in this *Bulletin*]

COVELL, G. NICOL, W. D., SHUTE, P. G. & MARION, M. Studies on a West African Strain of *Plasmodium falciparum* II The Efficacy of Paludrine (Proguanil) as a Therapeutic Agent *Trans. Roy. Soc. Trop. Med. & Hyg.* 1949, Mar., v 42, No 5, 465-76, 1 chart [10 refs.]

The authors describe therapeutic trials with paludrine, carried out at Horton, with a W. African strain of *P. falciparum* whose origin was described in Pt 1 of this series [this *Bulletin*, 1949, v 46, 437] The object was to clarify some outstanding questions with regard to treatment of infections with this strain During maintenance of the strain by serial blood and mosquito transmission (*A. stephensi* from India were used), it was only in contact with paludrine on one occasion All the patients were neurosyphilitics who had undergone malarial therapy 9 or more years earlier Successful trials of this drug with W. African and New Guinea strains of *P. falciparum* have previously been reported [this *Bulletin*, 1946, v 43, 402, 527, 1947, v 44, 282] In Malaya and India results were not so satisfactory In Sardinia, BETTINI [this *Bulletin*, 1948, v 45, 861] found that the clinical response in malignant tertian infections was satisfactory, but relapses occurred At Horton 31 patients were inoculated intravenously with sporozoites from two infected mosquitoes of the same batch It appeared that the numbers of sporozoites injected did not appreciably affect the severity of the attack or the number of relapses The patients were divided into 6 groups and, when temperatures reached 100°F and parasites were present in the peripheral blood, treatment was given as shown —

Group	Number in each group	System of Treatment	Result
1	5	Paludrine mgm. 300 once daily for 14 days	All relapsed within 3 weeks. One had second relapse after further treatment.
2	5	Paludrine mgm. 300 twice daily for 7 days	4-5 relapsed within 3 weeks and when re-treated there were further relapses.
3	8	Paludrine mgm. 300 twice daily for 10 days, plus mepacrine mgm. 300 thrice daily on the first day only	No relapse over 6 months.
4	5	Paludrine mgm. 300 twice daily for 10 days, plus quinine hydrochloride grains 10 thrice daily on the first day only	No relapse over 6 months.
5	5	Quinine hydrochloride grains 10 twice daily for 10 days	No relapse over 6 months.
	2	Quinine hydrochloride grains 10 thrice daily on one day only	The rapidity of clinical response was in the order mepacrine paludrine quinine.
6	2	Mepacrine mgm. 300 thrice on one day only	For clinical reasons the treatment outlined was not adhered to.
	2	Paludrine mgm. 300 thrice on one day only	

Gametocytes disappeared from the blood of all patients except one treated with paludrine and quinine. In those who had relapses gametocytes were present except in one case. Paludrine was effective in controlling the clinical attack as other authors have found, but asexual parasites disappeared from the peripheral blood more slowly than after treatment with mepacrine or quinine. Unlike FAIRLEY who used a New Guinea strain of the parasite and obtained a radical cure in 46 out of 47 cases the present author was unable to effect radical cure with the Lagos strain. The series is small, and it is possible that the relapses are associated with early treatment of the primary attack in absence of immunity. Because of the favourable results obtained by reinforcing paludrine treatment with mepacrine such a course is recommended in all cases of this potentially dangerous infection. The replacement of mepacrine by quinine is not recommended although both drugs helped to prevent relapses. As found by other authors paludrine prevented development of gametocytes in mosquitoes. The following paragraph is taken from the authors' summary—

"It is considered that a course of paludrine (mg. 300) twice daily for 10 days, reinforced with mepacrine (mg. 300) given in three doses on the first day of

treatment and followed by a maintenance dose of paludrine mg 100 daily for the ensuing 6 weeks would fulfil the main objectives in the treatment of falciparum malaria, namely, rapid termination of the clinical attack, a high radical cure rate, sterilization of gametocytes and minimum risk of injurious side effects "

J D Fulton

ABBOTT, P H Proguanil in the Sudan [Correspondence] *Brit Med J* 1949, Mar 5, 413-14

The writer of this letter states that he has found proguanil (paludrine) to be a very valuable malaria prophylactic in his district of the Southern Sudan where *P falciparum* malaria is hyperendemic For the last two years it has afforded very adequate protection to a number of British officials and Northern Sudanese Arabs who have been under his care If 350 mgm per week be taken regularly (half a tablet each morning at breakfast time) the chances of developing a clinical attack of malaria are very small indeed In the treatment of *P falciparum* malaria proguanil has, however, given disappointing results Doses of 100 mgm thrice daily for ten days reduce the fever less rapidly than does either quinine or mepacrine positive blood films have been found on the fifth day of such a régime

Norman White

FERRO-LUZZI, G Nuovi esperimenti sul trattamento paludrinico della terzana maligna in Eritrea [Further Experiments on the Treatment of *P falciparum* Malaria with Paludrine in Eritrea] *Bol Soc Ital di Med e Igiene Trop* (Sez Eritrea) 1948, v 8, Nos 5/6, 209-14 English summary

The author has previously reported the failure of paludrine in doses of 0.2 to 0.3 gm a day for ten days in the treatment of patients suffering from *P falciparum* malaria in Eritrea [this *Bulletin*, 1949, v 46, 213] In this paper he records the results of the treatment of 50 additional patients with 0.6 gm paludrine a day for ten days, and 50 patients with mepacrine for seven days and pamaquin for a further five days There was little if anything to choose between the two methods of treatment with regard to the duration of fever or the persistence of trophozoites in the blood With regard to the relapse rate, however, paludrine showed up badly Within 20 days from the end of treatment with paludrine 34 per cent of the patients relapsed, as compared with 2 per cent after mepacrine-pamaquin treatment It is suggested that the local Eritrean strains of *P falciparum* have a particular resistance against paludrine

Norman White

CANET, J Efficacité comparée de la nivaquine et de la paludrine dans le traitement curatif de l'accès palustre aigu, en Indochine [Comparative Efficacy of Nivaquine and Paludrine in the Treatment of Acute Malaria in Indo-China] *Bull Soc Path Exot* 1948, v 41, Nos 11/12, 661-6

In a hospital in Indo-China, 140 patients suffering from acute attacks of malaria were treated with nivaquine, and 140 with paludrine The dose of each drug was 0.30 gm a day The two groups of patients were comparable in each there were 120 *P falciparum* and 20 *P vivax* infections Both drugs were effective, but the action of nivaquine was more rapid than that of paludrine both as regards the control of fever and the rate of disappearance of schizonts from the peripheral blood On the morning of the third day 93 per cent of the *P falciparum* patients treated with nivaquine were afebrile as compared with 66 per cent of the paludrine-treated patients On the fourth evening 76 per cent of the nivaquine *P falciparum* patients were free from demonstrable parasites as compared with 60 per cent of the paludrine group Similarly with

the *P. vivax* infections on the third evening 85 per cent of the nivaquine patients were afebrile as compared with 70 per cent of the paludrine patients on the sixth day 45 per cent. of patients receiving paludrine harboured parasites as compared with 5 per cent. of the nivaquine treated patients.

Neither drug had any action against the sexual forms of *P. falciparum* and nivaquine none against sexual forms of *P. vivax*. The possible activity of paludrine against *P. vivax* gametocytes calls for further inquiry.

The curative action of nivaquine on the general symptoms of acute malaria was more prompt and more constant than was that of paludrine.

Both drugs were equally well supported. Symptoms of intolerance were rare and insignificant. The author considers both drugs to be a distinct advance on older synthetic remedies such as mepazine.

CROGGESHALL, L. T. & RICE, F. A. Cure of Chronic Vivax Malaria with Pentaquine. *J Amer Med Ass* 1949 Feb. 1., v 139 No. 7 437-8.

This paper reports the treatment of 185 ex-servicemen, suffering from relapsing vivax malaria with pentaquine and quinine. Pentaquine is a derivative of pamaquin than which it is less toxic and more effective. Infection in 154 of these men had been acquired in the South-west Pacific. The majority had been suffering from relapses every four to six weeks before treatment began. Pentaquine 30 mgm. and quinine 2 gm. were given daily for 14 days later the dose of quinine was reduced to 1.0 gm. daily. The reduced doses of quinine were given in 67 cases and proved to be as effective as the larger doses. After treatment the patients were observed for six months or longer. In only ten was a further relapse noted, with parasites in the blood. Ten others had chills but no parasites could be found in their blood smears. One hundred and sixty three have had no further symptoms referable to malaria. A striking relief from the subject's symptoms associated with chronic malaria was experienced by nearly all. The treatment was ambulatory and did not necessitate interruption of normal activities. Toxic reactions were largely those associated with the use of quinine.

DAVEY, F. & SMITH, M. Malaria Prophylaxis with Proguanil. (Correspondence) *Brit Med J* 1949 May 28 856.

The writers of this letter refer to reports of *falciparum* malaria occurring in persons taking more than 0.1 gm. of proguanil on alternate days this March 1949 v 45 477. *Brit Med J* 1949 Feb 10 724 and the recommendations

of these authors, implemented by the Colonial Medical Research Committee [thus *Bulletin*, 1949, v 46, 608], that the prophylactic dose of proguanil should be 0.1 gm daily

They then describe a case in an endemic area in Nigeria where malaria due to *P. falciparum* occurred in a European nursing sister who had been taking 0.1 gm of proguanil daily as a prophylactic

The patient had been in Nigeria for nine months, and during the whole of that time had only occasionally missed taking a regular daily tablet of proguanil—at most this omission amounted to one a week and usually much less than this. She had had several mild and short attacks of pyrexia and in the absence of proved parasitaemia and because of their clinical nature the attacks were considered to be caused by a dengue-like fever. After the last attack she increased her dose of proguanil to 0.2 gm daily for eight days and then reverted to 0.1 gm daily

A month later, she developed an evening temperature of 101°F. Thick blood films then revealed the presence of 2 to 20 young *P. falciparum* trophozoites per microscopic field. Thin films showed some red cells with two or three parasites, some parasites with double chromatin dots and the presence of accolé forms, a picture typical of the acute *falciparum* infection seen locally in children

Increased proguanil and mepacrine aborted the attack and the temperature fell and remained normal from the next day. On the 14th day of the attack, gametocytes were found in the blood

It seems clear that in this case a daily dose of 0.1 gm of proguanil was insufficient to prevent a break-through of *falciparum* malaria

BERBERIAN, D A & DENNIS, E W. Field Experiments with Chloroquine Diphosphate. *Amer J Trop Med* 1948, Nov, v 28, No 6, 755-76, 1 chart

The observations recorded were designed to test the value of chloroquine diphosphate in the treatment and prevention of malaria in rural communities. For this purpose two villages in Lebanon, Saideh and Azouniyeh, were selected. Malaria is hyperendemic in both, the transmission season lasting from the end of April to the end of November. *A. sacharovi* is the chief vector in Saideh, in Azouniyeh *A. superpictus* is predominant, but *A. claviger* and *A. martensi* also occur. The populations of the villages number about 215 and 200 respectively

In Saideh 93 persons were examined on August 25, 1946. These included all who were acutely ill on that day, those who had been ill recently and those who agreed to take suppressive treatment. Twenty-six of these persons were febrile and were each given a therapeutic course of chloroquine diphosphate. The remainder each received a single suppressive dose of the drug. This procedure was repeated at weekly intervals. On each occasion the numerous cases of fever that occurred among the "control" group of the population were treated and other members of the control group demanded and received suppressive medication. By November 18 all the villagers were receiving weekly suppressive doses of chloroquine diphosphate. This was continued till April 7, 1947. During the period of observation 70 attacks of malaria occurred among the diminishing control group, there were no attacks among those on suppressive medication.

The therapeutic dosage was for children under five years a total dose of 2½ tablets (0.25 gm each) spread over three days, for children 5 to 10 a total dose of 2½ to 5 tablets, for older ages a total of 5 tablets. This adult dose was insufficient in 7 of 45 cases, 3 *P. vivax* and 4 *P. falciparum* infections. In these cases a second course was given comprising double the dose prescribed for the

first treatment. The adult suppressive dose was 0.5 gm. * tablets, in a single dose once a week.

When chloroquin suppression ceased on April 7 an intensive treatment of the village with DDT started. The DDT treatment was repeated in July. During the period April 8 to November 23 1947 only three cases of malaria occurred in Saldich, two in May and one in June. Two of these were recurrences and one probably a fresh infection.

Observations in Azounyeh were on somewhat different lines but they support the conclusion that chloroquine diphosphate is a most effective curative and suppressive drug for malaria as it occurs in the Middle East. It is effective against *P. m.* as *P. falciparum* and *P. malariae*. Effective doses may be given to infants and during the course of pregnancy. By combining weekly prophylactic medication with DDT measures it is possible to eradicate malaria from a community within the period of a single transmission season.

Norman H. Aik

STIERLI H & STENBURG, R. L. Some Developments in Insecticide Dispersion Equipment. *J. National Malaria Soc.* 1949 Mar v 8 No. 1 100-108 7 figs.

There is a need for the improvement of equipment for spraying insecticides and the author considers several defects in common equipment and the means of remedying them. The hand-pump sprayers of the knapsack type are very wasteful of operators' time and some form of mechanical air compressor to charge tanks as car tyres are commonly charged is considered essential in any efficient scheme. Aluminium is better than other metals for the manufacture of tanks, and there is need for improvement in housing shut-off valves and other parts.

Several types of sprayer made from surplus war materials, such as aircraft compressed-air tanks are described together with a new design made from fresh material. In essence it consists of two cylindrical aluminium tanks of 6½ in. and 8 in. diameter the smaller holding 2 gallons of fluid is situated within the larger the space between acting as the air reservoir. It is given an initial charge of 80 lb. per sq. inch and will discharge the liquid contents at a constant pressure of 40 lb. per sq. inch. A modification of a previous shut-off valve which has quick action and prevents leakage round the release pin is described. Brief information is given about an "Institution Sprayer" with an electric or petrol power unit suitable for the routine treatment of hospital wards, warehouses and large buildings, and of a "Multi-Purpose Insecticide-Dispensing Machine" which consists of a collection of apparatus on a truck capable of undertaking a wide range of insecticide work including the distribution of dust and liquid. The modifications proposed seem sound and the apparatus described is probably a considerable advance. In the absence of scale drawings it is only possible to understand and not to re-duplicate the designs. (Mardon)

FERGUSON F F UPROOT W M & INMUNA S W A Summary of the Experimental Use of DDT as a Mosquito Larvicide. *J. National Malaria Soc.* 1949 Mar v 8 No. 1 32-49 140 refs.

This is itself a highly condensed summary. It consists of a classified account of the literature on the use of DDT as a mosquito larvicide with very full bibliography with some authoritative opinions on present trends in practice. It could be consulted in the original by all interested in the subject.

The account covers all aspects of the subject and a few outstanding points may usefully be listed. United States authorities recommend that the dosage should not exceed 0.1 lb DDT per acre. Where reasonable precautions are taken DDT larvicides may be used without danger to the health of workers. Though larvae are extremely susceptible to DDT, pupae are very resistant. Residual larvicide action has not been achieved except under exceptional conditions, the explanation propounded being that DDT is absorbed upon the organic soil components of a pond-bottom complex. There is no significant difference between the susceptibility of different types of larvae. Pond wild life may readily be destroyed by DDT, particularly by emulsions, unless great care is used. Of the many methods of application used the author considers that the oil/mist technique described by FERGUSON *et al* [this *Bulletin*, 1947, v 44, 645] is possibly the most effective manual method. Several references are given to air distribution and to the effect of particle size and its measurement.

The author considers that future development in the field of DDT liquid larviciding may be chiefly centred in basic studies of the type of solvent and solvent spraying agent, and continued efforts to improve dispersion equipment.

G Macdonald

NAIR, C. P. Effect of DDT Barrier Spray in *A. sundanicus* Area in Malaya. *Med J Malaya* 1949, Mar, v 3, No 3, 198-203, 1 map.

DDT as a 5 per cent solution in kerosene was applied as a barrier spray to a strip of ground 50 yards broad around experimental sites. The dose was 6 gallons per acre (1.1 oz DDT per 1,000 sq ft) and the fluid was applied from hand atomizing sprayers on a carefully regulated technique. In one experimental area the barrier spray only was applied. In the second it was supplemented by spraying the external walls of the houses up to a height of 7 ft. In the third it was supplemented by this same external spray and an internal house spray delivered from atomizing guns in the manner common with the use of immediate insecticides. Comparable groups of houses were left as untreated controls.

Mosquito catches showed an immediate disappearance of anophelines (presumably mostly *A. sundanicus*), and a marked reduction in culicines. Observation was stopped when the anophelines in the treated houses reached one-tenth of the number in the untreated, and this occurred between 9 and 14 days, there being no difference in the three areas.

SCHMIDT, L. H., GENTHER, Clara S., FRADKIN, Rochelle & SQUIRES, Wanda. Development of Resistance to Chlorguanide (Paludrine) during Treatment of Infections with *Plasmodium cynomolgi*. *J Pharm & Exper Therap* 1949, Mar, v 95, No 3, 382-98, 4 figs [14 refs].

While studying the effects of chlorguanide [paludrine] on blood-induced infections of *P. cynomolgi* in rhesus monkeys it was noted that hosts which had earlier been treated with small amounts of the drug were no longer freed from infection by doses normally curative. The strain showed stable characters to other antimalarials. In the experiments now described, infection was also produced by intravenous inoculation of sporozoites from *A. quadrimaculatus*. Drugs were given in aqueous solution by stomach tube twice daily for 7 or 14 days. Blood smears were examined in thick and thin films, and the proportion of the different parasite stages noted. If parasites remained absent from the blood for 8 weeks or more after treatment and failed to reappear within 4 weeks after splenectomy the animal was considered to be cured.

Doses of 0.075 mgm. paludrine or less per kilo were able to suppress parvartemia and 0.4 mgm. per kilo effected cure in more than 90 per cent of cases. It should be noted that in rhesus monkeys this infection is self-limiting within a period of 4 months. Resistance was produced to paludrine by the classical method of serial passage and use of gradually increasing sub-curative doses.

After passage through three monkeys from a host with partially resistant parasites it was found that the maximally tolerated dose of 40 mgm. per kilo of paludrine was non-curative and did not appreciably affect the course of infection thereby indicating a 2,000-fold resistance. [In this connexion the authors note that only a four fold resistance to plasmoquine was obtained in *P. knowlesi* infections of rhesus monkeys (this Bulletin 1942, v 30, 426). It should be observed however that plasmoquine is a toxic drug and as in their case the maximum tolerated dose did not influence the infection.] Whereas in the normal strain (*P. cynomolgi*) the drug allowed the development of schizonts but prevented segmentation, in the resistant strain growth and reproduction were unaffected, and morphological changes in the parasites were absent. The resistant character persisted unchanged after mosquito passage and likewise after 6 blood passages over a period of 5 months. The resistance to paludrine did not involve resistance to chloroquine or quinine in blood induced infections, or to pentamidine in sporozoite-induced infections. No evidence was obtained of induced resistance to quinine atabrin (quinacrine) chloroquine oxychloroquine pamaquin pentamidine or isopentamidine. The authors believe that these drugs attack the parasite in a different way from paludrine.

A brief discussion is given of the implications of this developed resistance to paludrine. The authors note specially that mature trophozoites and early schizonts of *P. cynomolgi* are affected by the drug without the accompanying morphological changes, which characterize the action of other antimalarials. Also the parasites in contact with paludrine remain for several days in the blood whereas after treatment with other drugs they may disappear in a few hours. They indicate a parallel to the readiness with which resistance of bacteria to the bacteriostatic sulphonamides is produced, as opposed to the difficulty of producing it by bactericidal penicillins. It is possible that the resistance produced in *P. cynomolgi* by paludrine may result from mutation.

[For evidence of acquired resistance in different plasmodia to quinine plasmoquine paludrine, see this Bulletin 1941 v 18, 86 1933 v 30, 860 1935 v 32, 116 1941 v 39, 438 1943 v 40, 754 1947 v 44, 869 970 1948 v 45, 158.]

RAGAN, H. A. Effect of Humidities and Temperatures on the Size and Number of Oocysts of *Plasmodium gallinaceum* transmitted by a Mosquito. [Correspondence.] Nature 1949 Apr 23 643-4

Aedes aegypti mosquitoes were infected by allowing them to feed upon chicks whose blood contained numerous gametocytes of *P. gallinaceum*. Batches of twenty of the engorged mosquitoes were then transferred to celluloid cylinders covered with netting and placed in jars of differing humidities, the humidity being controlled by mixtures of sulphuric acid and water at 50, 70 and 70 per cent. Three of each cylinders were kept at 25°C. three others at 18°C. (A relative humidity of 30 per cent. or of 80 per cent. caused the mosquitoes to die rapidly.) On the sixth day all the mosquitoes remaining alive were dissected and the results were as follows:—

	18°C			25°C		
Relative humidity	50	60	70	50	60	70
Number of mosquitoes	12	17	15	13	16	14
Mean number of oöcysts	11	29	29	11	33	32

The different humidities did not affect the size of the oöcysts (the size was, however, affected to a small degree by the temperature, those kept at 25°C being about 20 per cent larger than those at 18°C), but they clearly had an action on the number of oöcysts, a low humidity reducing the number to nearly a third of the numbers occurring at 60 or 70 per cent. It is stressed that in nature where mosquitoes have access to drinking water, a low humidity in the external environment might not have this effect.

[The optimum conditions for the development of different plasmodia in species of mosquitoes are still imperfectly known, studies such as this are, therefore, valuable]

GRAY, A & HILL, J. Antimalarial Studies in the Quinoline Series. *Ann Trop Med & Parasit* 1949, Apr, v 43, No 1, 32-8 [18 refs]

The activity of a number of quinoline derivatives has been tested in blood—induced and sporozoite—induced infections of *P. gallinaceum* in which methods already described [this *Bulletin*, 1946, v 43, 394] were used, and in blood-induced infections of *P. relictum* by the method of Roehl. When pamaquin (plasmaquine), pentaquine and R36 (8-γ-aminopropylamino-6-methoxy quinoline) were converted to the 1,2,3,4-tetrahydro derivatives it was found that they were less active than the unreduced compounds. Toxicity was also reduced in the first two substances by this treatment. The compound R36 was originally shown by TATE & VINCENT [this *Bulletin*, 1934, v 31, 434] to possess considerable activity in *P. relictum* infections of canaries and is also very active against *P. gallinaceum*. The present authors believe that its presence as an impurity is largely responsible for the activity of the related substance R63. This latter compound, as used by the authors, was considerably less active than pamaquin in both infections. The activity of a number of compounds related to the 4-aminoquinoline chloroquine [this *Bulletin*, 1946, v 43, 708] and its 3-methyl derivative sontoquin, both of which were originally synthesized in Germany and later studied intensively in America, has also been investigated. It was found that the greatest activity was present in derivatives with the chlorine atom in position 7 in the quinoline nucleus as in chloroquine itself. Activity was reduced by the introduction of one (sontoquin) or two methyl groups.

SAMPATH A. & LITTLE, P. Cultivation of *Trypanosoma cruzi* in Liquid Media. *J. Bacteriology* 1949 Feb. v 57 No. 2, 265

The junior author with SREBRAROW [this *Bull.* 1948, v 43 538] described a liquid medium for the cultivation of *Trypanosoma cruzi*. For two years, they have now been using a more enriched basal medium with the use of which they are able to grow *T. cruzi* in the coagulum-free filtrate obtained by extracting fresh coagulum of rabbit red blood cells with basal medium.

The enriched medium has the following formula —

1	Peptone (Difco)
1	" Casamino acids "
0.5	Sodium chloride
0.2	Glucose
10 mgm.	β -Alanine
10	Glycine
2	" Folic acid
2	" Nicotinamide
2	Thiamine
2	" Choline

Optional 1 per cent corn steep liquor free of alkaline precipitate (The corn steep liquor was adjusted to an alkaline pH filtered, and neutralized before use. It prolonged the viability of cultures.)

This has been found better than the original medium for certain strains of *T. cruzi*. It may be used with the rabbit-blood coagulum already described or the medium may be activated by the addition of 10 grs. of semi-dry fresh coagulum per 100 cc. The whole is mixed in a Waring blender and filtered. The activated filtrate remains stable after autoclaving and may be kept in a refrigerator for several months. *II J. O'D. Burke-Gaffney*

LEISHMANIASIS

RAMOS E SILVA, J. Leishmaníase. Considerações sobre a forma generalizada da leishmaníase tegumentar americana. Leishmaníase a Generalized Form of American Cutaneous Leishmaniasis. *B. San. St. São Paulo* 1949 Jan. 22 & 29 v 61 No. 45 23-6 3 figs. English summary

Multiple lesions of cutaneous leishmaniasis are usually the result of auto-inoculation by digital transfer or of multiple infections. Here the author

records the case of a man of 53 years with an initial espundia sore on the left leg, followed by two sores of the hip and chin, possibly, even probably, caused by auto-inoculation and digital transfer. These were succeeded by lesions on the neck, trunk (back and front) and arms, furunculoid in appearance, with a lymphangitis and adenitis. Wassermann reaction was negative and beneath the crusts of the lesions abundant leishmania could be found. These disseminated papulo-pustular lesions appeared about two months after the primary lesion. Though the facial sores were probably the result of auto-inoculation, the presence of lymphangitis and lymphadenitis indicates extension by the lymphatics and the wide dissemination may be ascribed to a spread by way of the blood-stream.

FEVERS OF THE TYPHUS GROUP

MEXICO Primera Reunion Interamericana del Tifo Mexico, D F 7-13 de octubre de 1945 [The First Inter-American Conference on Typhus] 455 pp, numerous figs 1947 Mexico

This volume contains a collection of papers read at the First Inter-American Conference on Typhus, which was held at Mexico City in October 1945.

Most of the papers would have been of great interest if they had been published soon after the holding of the conference, but the great delay in publication is not so unfortunate as it would have been if the contributors had not published the substance of their articles elsewhere.

The papers on the distribution of the fevers of the typhus group in various countries of the American Continent will be of interest to students of the geographical distribution of the diseases. The name typhus is used in its broad sense by most of the contributors, and so includes the tick-borne disease which, though called by different names, is now regarded as being the same as Rocky Mountain spotted fever throughout the American Continent.

The list of authors is impressive, it contains such well-known names as Amigstein, Camargo, Castañeda, Cox, Craigie, Dyer, Macchiavello, Pinkerton, the late Col Plotz, Soper, and Topping, but there is little in their contributions that has not been reviewed in this *Bulletin*.

In view of the controversy that has arisen in connexion with priority for the initiation of mass-dusting of fully clothed persons by insecticide dusts, a brief reference may be made to the paper by F L SOPER, F S MARKHAM, W A DAVIS and L A RIEHL on their Experience with Powders in the Control of Typhus in Italy, 1943 to 1945. These workers were members of the Rockefeller Foundation Typhus Team, and after experiments in Egypt early in 1943, which proved that insecticide powders could be used with success for mass delousing of clothing, they went on in July, 1943 to test MYL and DDT powders at the Maison Carrée Prison, Algiers, where they found that the powders could be satisfactorily applied with hand dusters or compressed-air units without removing the clothing from the body. They state that this work was very important since it was the basis of the proposal, made in the initial discussion with the Military Government Section of the A I H Q, to undertake control of typhus fever in occupied Italy with louse powder alone. This proposal was put into effect with startling success in Naples in December, 1943, and although vaccination was also adopted in January, 1944, this came too late to have any significant influence on the course of the epidemic. The authors emphasize the ease with which louse infestation, and so typhus transmission, can be controlled in this way.

of formalized horse-serum produced a reduction in the rickettsia-agglutination titre of the fluid by about one-half

John H. D. Meyer

URGENT Ed., BÉGUTY M., PARROT L. & HORRENEFENGER R. La prophylaxie du typhus exanthématique en temps d'épidémie et dans les périodes inter-épidémiques en Algérie [The Prevention of Exanthematic Typhus in Epidemic and Interepidemic Periods.] *Arch. Inst. Pasteur d'Algérie* 1949 Mar. v. 27 No. 1 1-8.

The authors were associated with the field experiment which formed the basis of the successful control of the famous Naples epidemic of 1943-44. They mention the trials of MYL and DDT carried out in collaboration with the Rockefeller Foundation team headed by F. L. SORRE at the Maison Carrée prison and in a rural area near Algiers during the first half of 1943 and state that "The Pasteur Institute of Algeria conceived the idea (major) of blowing the powder under the clothing."

The methods recommended in Algeria are (1) During epidemics vaccination with killed vaccines and dusting all persons exposed to risk of infection, employing insecticide powders, and (2) During interepidemic periods the yearly vaccination of the inhabitants of endemic areas, without using insecticide powders. The omission of dusting except during epidemics is presumably based on the principle of making the best use of the available staff and materials apart from this consideration it would appear advisable to maintain low control at all times in endemic areas.

Vaccination with a single dose of the killed vaccine of Durand and Giroud is recommended. It is carried out simultaneously with smallpox vaccination and antituberculous inoculation with B.C.G. so that the health staff can deal with the prevention of three great diseases at the same time. (See also this Bulletin 1949 v. 48 539)

CHAUDHURI R. N. & CHAKRAVARTI H. Typhus in Calcutta. *Ind. J. Med. Gaz.* 1949 Feb. v. 84 No. 2, 43-51 3 figs. [15 refs.]

The author gives a good clinical description of 25 cases of "typhus fever" studied in a Calcutta hospital during the previous 37 months. Four of the cases were diagnosed as murine typhus (OX19) and 21 as mite typhus (OXh). There were two deaths. The patients were closely observed and the clinical features as described were in keeping with the diagnosis of fevers of the typhus group. Two of the patients had eschars, seven had enlarged glands in the neck. The white-cell count was usually within normal limits. There was hypoproteinaemia in most of the cases, the defect being in the albumin fraction.

Among the cases of the OXh type, one gave a negative reaction in each of four weekly Weil-Felix tests, though rickettsiae were recovered from the blood. This was a case of laboratory infection resulting from the bite by a mouse which was being inoculated with a typhus emulsion. There was a whitish-like eschar at the site of the bite.

In the other OXh cases titres 1:100 to 1:1,800 were observed

John H. D. Meyer

BRICEÑO-IRAGORRY L. Estudio sobre 4,203 reacciones d Weil-Felix en sujetos d febricitantes de la zona de Caracas. Study of 4,203 Weil-Felix Reactions in Cases of Fever in the Caracas Area. *Rev. Sanidad y Asistencia Social* Caracas, 1945 Apr. 10 No. 3 p. 17.

The 4,203 sera were from persons suspected of having typhoid fever. During the five-year period, 1940-1944 in which the tests were carried out 41 cases of

murine typhus were diagnosed by the reaction, these are discussed separately. The sera were tested first by a rapid slide method and the positives were further tested by the standard method.

The number of sera reacting with *Proteus OX19* at titres of 1-40 or over was 365 (8.4 per cent). Reactions at titres of 1-160 and 1-320 are specially discussed. There were 31 (0.73 per cent) at the former titre and 25 of these also reacted at titres of 1-40 to 1-320 against an O strain of typhoid bacilli, leaving only six cases in which the Weil-Felix reaction could not be explained either as a para-agglutination in cases of typhoid fever or as a typhus reaction. In all the 7 cases in which the titre was 1-320 the Widal reaction was also positive at titres of 1-160 to 1-320, and the diagnosis of typhoid fever was established so the Weil-Felix reactions were regarded as para-agglutinations.

In the 41 cases of murine typhus already mentioned the Weil-Felix titres ranged from 1-200 to 1-10,000, and only one gave a positive Widal reaction against an O strain, of typhoid, and that was at a titre of 1-40. There were a few reactions against an H strain, against paratyphoid B and C, but never at a titre higher than 1-80.

The conclusions reached were—(1) Weil-Felix titres of 1-80 or less have no diagnostic significance unless the titre is found to be rising, (2) A titre of 1-160 in the absence of a positive Widal reaction is suspicious and calls for further investigation, (3) A titre of 1-320, unless accompanied by a positive Widal reaction, is regarded as diagnostic, (4) In typhus fever there is little tendency to the development of typhoid agglutinins, whereas in typhoid fever there may be a pronounced tendency to the production of agglutinins against *Proteus OX19*.

[The last conclusion is contrary to the experience of most of the other workers on the subject.]

John W D Megaw

VARELA, G, PÉREZ-REBELO, R, ROCH, E & OLARTE, J. Exploración de tifo en ratas de la ciudad de Mexico, por medio de la fijación del complemento con rickettsias y aglutinación con *Proteus OX19* [Survey of the Prevalence of Typhus Infection of Rats in Mexico City, by Complement-Fixation and Weil-Felix Tests] *Rev Inst Salubridad y Enfermedades Trop* Mexico 1948, June, v 9, No 2, 139-44. English summary.

Complement-fixation tests, with the use of murine antigen, were carried out on 1,376 rats trapped in Mexico City between March and September, 1948. In 9.7 per cent of these, positive results were observed. In most cases the reactions with epidemic antigen were also positive, but always at titres of one-half or less when compared with the reactions against murine antigen.

In another series of 1,157 rats Weil-Felix tests were carried out. Against *Proteus OX19* there were 12.2 per cent of positives, and in about one-third of these there were positive reactions against *Pr OXK* or *Pr OX2* or both. Against *Pr OXK*, 7.9 per cent of the rats gave positive reactions and against *Pr OX2*, 3.5 per cent reacted, in both of these groups about one-half of the reacting animals were positive also with one or both of the other *Proteus* strains. Altogether 18.7 per cent of the rats agglutinated one or more *Proteus* strains at titres of 1-80 or over.

KRISHNAN, K V, SMITH, R. O A, BOSE, P N, NEOGY, K N, ROY, B K G & GHOSH, M. Clinical Features and Laboratory Diagnosis of XK or Mite-borne Typhus as observed in 102 Cases in the Barrackpore Area. *Indian Med Gaz* 1949, Feb, v 84, No 2, 33-9, 3 charts.

This is the first of a series of four papers by the Bengal Typhus Enquiry team, based on the All India Institute of Hygiene, Calcutta.

During the years 1946-48 102 cases occurring at Barrackpore near Calcutta were diagnosed as "typhus fever". The case-fatality rate was 3.0 per cent.

In 64 of the cases the diagnosis was confirmed by the Weil-Felix test and by isolation of rickettsiae from inoculated animals. Serologically 72 per cent. of the cases were of the XK type 19 per cent were of the X19 (murine) type and 9.0 per cent of the X₂ type.

It was not possible to differentiate the three serological types on clinical grounds. A description is given of the clinical features of the XK cases. 80 per cent. of these were mild and no eschar was detected in any of them. 20 per cent. were severe. In 5 of them there was an eschar. A rash was seen in 7.0 per cent. of the mild cases, and in 75 per cent. of the severe. In the mild cases the diagnosis of a typhus-group fever was usually impossible on purely clinical grounds.

In the X19 cases the Weil-Felix titre always rose to 150 or over but guinea pig inoculation carried out in some of the cases never caused a Neill-Moser reaction.

In the XK cases the Weil-Felix reaction was completely positive in 10 per cent. It reached titres of only 125 or 1-50 in 25 per cent. in 63 per cent. the titre was 1/100 or over.

There were 7 cases of the X₂ type all of which had titres of 1/125 or over and all reacted also with OXK or OX19 at titres of 1/25 or 1-50. The authors rightly suggest that this type needs to be properly investigated, especially as animal inoculation has not been very helpful.

Washed blood cells from the XK cases were used for the inoculation of white mice in which ascites always occurred in the positive cases whereas "by no other strain studied was it caused". Inoculated mice when positive always yielded viable rickettsiae from peritoneal scrapings taken about the 8th day.

Mice inoculated with the blood of one of the X₂ patients reacted in the same way as those inoculated from XK patients so that this strain was assumed to be one of XK and not of X₂ whereas blood of another X₂ patient caused an apparent infection in a mouse and guinea pig but a strain of rickettsia was isolated by subinoculation with spleen and brain material, and this was subsequently passed through guinea pigs. The comment made is that this strain may be considered to be an X₂ strain of this area.

Suitable antigens were not available for complement fixation tests which, however, were not regarded as being very necessary except in connexion with the X₂ cases.

[Few workers on the typhus fevers would regard the complement fixation tests as superfluous in such conditions. It would be easy to submit sera from one of the American laboratories specializing in the test.]

In view of their own findings it is surprising that the authors lay stress to such lengths in their attempt to correlate the classification based on the Weil-Felix response with the recognized classifications. The OX19 type includes not only louse-borne and flea-borne typhus but also many cases of tick-borne typhus. 35 per cent. of the present cases had XK type and did not give significant reactions with Proteus OXK and one case giving an X₂ reaction is said really to belong to the XK group. Boyd who first employed the classification based on the Weil-Felix response never claimed any significance for this except as a statement of the fact that sera from various parts of India gave certain responses and he was not classifying the types of disease but only the types of reaction.

KRISHNAN, K V, SMITH R O A, BOSE, P N, NEOGY, K N, ROY, B K G & GHOSH, M The Breeding and Maintenance of *Trombicula deliensis* in the Laboratory for Experimental Purposes *Indian Med Gaz* 1949, Feb, v 84, No 2, 39-41, 1 pl

This paper will be read with great interest by all workers on the vectors of mite-borne typhus. The authors are to be congratulated on their remarkable success in breeding *Trombicula deliensis* in the laboratory.

Ingenious methods are described by which three complete generations of the mites have been reared starting from a colony collected from local rats.

A few mites collected in June 1948 were still alive and breeding five months later. A brief description of all the stages in the life cycle is given, and is illustrated by an excellent plate showing photomicrographs of each stage. In the following list of the stages the approximate duration of each, in the conditions described, is shown in brackets. Egg (7 days), deutovum (7 days), larva (3-5 days), nymphochrysalis (7 days), nymph (7-14 days), imago-chrysalis (7 days), and adult.

The special importance of this study is that for the first time it places at the disposal of other workers a method of obtaining laboratory-bred mites in sufficient numbers for employment in transmission experiments.

The initial success in rearing the larval mites was due to the adoption of the method used by WHARTON and CARVER who fed nymphs of *Neoschöngastia* mites on insect eggs [see this *Bulletin*, 1946, v 43, 1079]. For details of the authors' methods the original paper must be consulted.

KRISHNAN, K V, SMITH, R O A, BOSE, P N, NEOGY, K N, ROY, B K G & GHOSH, M Transmission of *Rickettsia orientalis* by the Bite of the Larvae of *Trombicula deliensis* *Indian Med Gaz* 1949, Feb, v 84, No 2, 41-3

As a happy sequel to their success in breeding mites in the laboratory, the authors are now able to report that they have transmitted *Rickettsia orientalis* from mouse to mouse in the laboratory by the bites of larval *Trombicula deliensis* which were the progeny of larvae infected by feeding on infected mice.

Five of the eight mice on which infected larvae had fed became infected, the infection was inapparent but was demonstrated by the recovery of strains from mice inoculated with brain suspensions of the fed mice.

The three mice which did not become infected had been bitten by 11 to 30 larvae, in the successful cases the mice had been bitten by 38 to 78 larvae. No natural infection could be detected in any mice of the strain used in the above experiments.

The paper contains a hint that experiments on the transmission of infection to human volunteers may be contemplated by the authors.

KRISHNAN, K V, SMITH, R O A, BOSE, P N, NEOGY, K N, ROY, B K G & GHOSH, M Epidemiological Observations on XK or Mite-borne Typhus in Barrackpore, Bengal *Indian Med Gaz* 1949, Feb, v 84, No 2, 63-8, 3 charts [12 refs]

This is a description of the epidemiological features of the fevers of the typhus group in Barrackpore, a cantonment town near Calcutta.

The disease was most prevalent during the rainy season, May to October, this was also the season of greatest abundance of *Trombicula deliensis*.

Most of the persons affected were workers or campers in the scrub jungle or fields. *T. deliensis* mites were found in large numbers on 74 per cent. of the local *Rattus* spp. and 20 per cent. of the highly infested rats were found infected with *Rickettsia orientalis*.

(The authors mention the case of laboratory infection described in the preceding paper by CHAUDHURI *et al.* (above) and state that the blood showed agglutinins for O.K. this is probably a mistake because the physicians in charge show the reaction as having been negative in tests made during each of the four weeks of the illness and they add that this result shows "the unreliability of this non-specific test.")

BROWNING, H. C. & HALRA, S. L. Scrub Typhus subsequent to "Fulton" Vaccine and Investigation of the Infected Area. *J. Surv. J. Med. Res.* 1949 Oct. v. 38 No. 4 279-80.

The greater part of this paper consists of a description of an epidemiological survey of an infected site at Palei in the Manipur State situated between Assam and Burma. There were 17 cases, one of which was fatal, of scrub typhus among 261 members of a Pioneer Force camped on the site during the months July to September 1943. The survey was carried out during the months September to November of the same year. It is a good example of the kind of investigation found by experience to be most suitable in suspected areas. Rats in cages were placed at different points as baits for larval mites, soil samples were searched, local rodents and other animals were captured and tested for infection by mouse inoculation.

Four strains of the rickettsia of scrub typhus were recovered from rats (a variety of *Rattus* spp.); three of the strains were recovered from the blood of the rats. One strain was recovered from four *Hydromys* *lamarum*, one strain from the only tree shrew (*Tupaia belangeri belangeri*) which was examined, and one strain from one of the twelve specimens of field mice caught in the area. Four strains were recovered from 70 batches of mites collected from rats and one strain from a mite found attached to a patient. *Trombicula deliensis* was the only species of mite present in all the batches from which infection was isolated. A strain was recovered from the blood of one of the authors (H. C. Browning) whose attack is described in detail.

A different species of rickettsia was recovered from ticks (*Haemaphysalis* *leachi*); this strain was found to be immunologically identical with the rickettsia of Rocky Mountain spotted fever but its virulence for guinea-pigs was very low. This is a significant observation: it shows that immunologically identical rickettsia of tick-borne typhus may differ sharply in their virulence for guinea-pigs.

The attack from which one of the authors suffered is of special interest because the patient had received three doses of the "Fulton" vaccine four-and-a-half months before the onset: the attack must have been severe: there was delirium and incoherence of speech for several days; the fever lasted 13 days and there were minor rises of temperature on the 15th and 16th days. Serum taken on the 19th day was sent to Dr. Toppeng at Bethesda U.S.A. and was reported as having a complement fixation titre of 1:51 against harp antigen, and a titre of 1:32 against Gullman antigen. The strain isolated from the patient gave complete cross-immunity with the other strains of *P. tularum* isolated in the area. The authors conclude that the course of the disease had not been modified by vaccination but they believe that the other evidence available on the subject suggests that the vaccine has some protective value though this is short-lived so that it is inadvisable to give

the advice of FULTON and JOYNER [this *Bulletin*, 1946, v 43, 435] who recommend that "booster" doses should be given every three months

The authors also recommend that in view of the immunological differences found to exist between strains from different areas vaccines should be polyvalent

The only precaution taken by the patient while working in the infected area was a daily hot bath with soaping and scrubbing of the skin within two hours of each visit to the suspected site. The authors' comment is that either this treatment does not remove attached mites, or mite attachment for less than six hours can convey infection, or mites remain on the clothing for two to six hours and then can attack

KOUWENAAR, W & ESSEVELD, H **The Nature of Immunity against Scrub Typhus in Guinea-Pigs** *Documenta Neerlandica et Indonesica de Morbis Tropicis* Amsterdam 1949, Mar, v 1, No 1, 34-40 [34 refs]

In a large series of experiments carried out in North Sumatra, the authors found that guineapigs convalescent from infection with 14 different strains of *R orientalis* remained immune against challenge with homologous or heterologous strains for long periods, in one case up to 708 days

Only one strain, isolated in Sumatra, differed from the others in failing to immunize against the other strains. The authors refer to the findings by BENGTON [this *Bulletin*, 1945, v 43, 551] and other workers of differences in the antigenic structure of various strains of *R orientalis*

Attempts to demonstrate the presence of protective antibodies in the sera of convalescent patients and guineapigs gave unsatisfactory results, large daily injections of the sera, started one or two days before inoculation, failed to modify the illness in guineapigs. When infected material was mixed with the serum before inoculation the fatality rate was 49 per cent, with similar doses mixed with normal serum it was 72 per cent, so there seemed to be some attenuation of the virulence of the infection

The persistence of viable rickettsiae in the recovered guineapigs was most easily demonstrable by inoculation with spleen substance, second best was blood, but brain, testicular tissue, and urine, gave more negative than positive results in the tests carried out 26 or more days after the end of the fever

The immunity is believed to be an "infection immunity" of the type described by SERGENT [*prémunition*]. The relatively brief immunity observed in man and monkeys is believed to be associated with the disappearance of rickettsiae from their bodies soon after recovery from the illness

UNITED PLANTING ASSOCIATION OF MALAYA **Scrub Typhus and its Prevention**
Prepared by the Scrub Typhus Research Unit at the Institute for Medical Research at the Request of the United Planting Association of Malaya
8 pp Kuala Lumpur

This pamphlet of eight pages was prepared by the Scrub Typhus Research Unit at Kuala Lumpur at the request of the United Planting Association of Malaya. It is a model of what such a pamphlet ought to be, containing as it does in simple language what every layman in Malaya needs to know and needs to do in connexion with the prevention of scrub typhus

The nature and manner of infection are described and the reader is told how to recognize the vectors by finding them as reddish or orange-coloured specks in the ears of infested rats. The harmless mites are described as being white or yellowish, and the mites that cause scrub itch in Malaya as bright scarlet in colour. As a rule of thumb it is advised that if half or more of the

rat trapped in an area are found infested steps must be taken to deal with the area in consultation with the officers of the Research Unit.

A point of interest is the statement that the available supply of chloromycetin is so small that the drug can be used only for the very urgent cases. It is also stated that the supply of vaccine produced as a wartime emergency measure is exhausted.

The chief measures of prevention mentioned are the treatment of clothing with dibutyl phthalate spraying dangerous areas marked down for clearance on the following day with crude oil at the rate of 40 gallons to the acre smearing the legs of labourers with the same oil and employing labourers who have already had an attack of the disease. Gammaxene applied as a dust at the rate of one pound to the acre is said to be "probably an effective agent" which however should not be applied without expert advice.

Warning is given that rat destruction should not be employed for the immediate control of infection though it is valuable as a long term policy.

ANDERSON J. R. Some Ecological Effects of Deforestation and Settlement. Reprinted from *Malayan Nature J.* 1948 Dec., v. 8, No. 4 178-89 3 figs.

This paper is of chief interest to naturalists, but it contains a significant reference to the special risk of scrub-typhus infection in the fringe habitats which are narrow zones at the periphery of forest clearings and which provide a combination of conditions favourable to the fauna of the forest as well as of the clearings. Hence the richness of the fringe habitats in the hosts of the mite vectors of scrub typhus.

HARRELL G. T. & AIKAWA J. K. Pathogenesis of Circulatory Failure in Rocky Mountain Spotted Fever. Alterations in the Blood Volume and the Thiocyanate Space at various Stages of the Disease. *Arch. Intern. Med.* 1949 Mar. v. 83 No. 3 331-47 13 figs. (Refs. in footnotes).

Systematic studies by biochemical and other methods were carried out in 13 cases of Rocky Mountain spotted fever, all of whom were given supportive treatment. In six of the cases antiserum or para-aminobenzoic acid or both were also given. The paper is illustrated by a set of elaborate charts showing the changes occurring in such features as pulse rate, blood pressure, plasma volume, thiocyanate space, total serum protein, serum albumin, etc.

The authors discuss the findings in each case. Some of the conclusions reached were—There is an increased permeability of the capillaries, especially during the second week of the rash. This is believed to be associated with the antigen-antibody reaction in the course of which histamine like body is produced causing an escape of fluid and proteins from the blood to the cells and tissues of the body and oedema. The maintenance of circulating proteins by feeding on a high protein diet is recommended in preference to transfusion. In two cases the unnecessary parenteral administration of serum, plasma or plasma caused an increase in plasma volume and myocardial circulatory failure.

The administration of para-aminobenzoic acid or antiserum did not prevent circulatory changes. The excessive administration of fluid may precipitate myocardial failure.

The general impression conveyed to the reader is that indiscriminate parenteral treatment is more likely to do harm than good and that patients who are given a generous diet well supplied with high-grade protein will rarely need transfusions of serum, plasma or whole blood. The authors

warning against giving excessive amounts of fluid should not deter physicians from giving adequate quantities, especially in the early stages of the illness

HARDY, S M A Review of Preliminary Clinical Studies on Aureomycin, a New Antibiotic Agent *Bol Asoc Med de Puerto Rico* 1948, Dec, v 40, No 12, 347-50 [14 refs]

This is a review of 14 papers (of which 9 are said to be "in the press" or "to be published") dealing with aureomycin. The drug is said to be particularly indicated in (1) the rickettsial diseases—tick fever, typhus, lymphopathia venereum, Q fever, psittacosis, ornithosis, and certain bacterial and viral eye infections [this is the author's classification], (2) primary atypical pneumonia, (3) genito-urinary tract infections due to penicillin-fast or streptomycin-fast organisms, (4) acute and chronic brucellosis, (5) streptococcus or staphylococcus or pneumococcus infections, especially those resistant to penicillin or streptomycin.

The usual method of administration is by the mouth, in doses of 25-100 mgm per kgm daily, for five to fourteen days. Parenteral injections are reserved for fulminating infections, the dose recommended is 2-10 mgm per kgm daily, but this "may be too low."

Verbal reports of two cases of death attributed to treatment are mentioned, one was apparently due to anaphylactic reaction after intravenous treatment, the other was with "an allegedly Hersheimer type of reaction" in a case of brucellosis.

ANIGSTEIN, L, WHITNEY, Dorothy M & BENINSON, J Aureomycin Protective Effect in Experimental Rocky Mountain Spotted Fever and Typhus with particular reference to Intermittent Treatment *Texas Reports on Biol & Med* 1949, v 7, No 1, 96-110

By a series of experiments on guineapigs inoculated intraperitoneally with *Rickettsia rickettsi* the authors have confirmed the findings already reported by WONG and COX (*Ann New York Acad Sci*, 1948, v 51, 290) and other workers, including themselves, with regard to the powerful anti-rickettsial action of aureomycin.

In the present experiments it was found that intermittent treatment with doses of 10 to 30 gm of the drug given every two or three days gave as good results as similar doses given daily. The intermittent treatment had less effect in preventing the development of high complement-fixation titres in the animals and so presumably interfered less with the production of immunity, but the recovered guineapigs were found immune when challenged with homologous rickettsiae even when the intermittent dosage had not been sufficient to cause complete suppression of the signs of infection.

DE MAGALHÃES, O & ROCHA, A Subsídio ao melhor conhecimento do tifo exantemático neotrópico no Brasil. Presença do vírus no leite [Contribution to the Better Knowledge of the Neotropical Typhus of Brazil] *Mem Inst Oswaldo Cruz* 1948, Mar, v 46, No 1, 269-83, 3 figs. English summary

The authors state that they have demonstrated the presence of the "virus of exanthematic neotropical typhus" [presumably *Rickettsia rickettsi*] in the milk of a goat which, three days previously, had been inoculated intraperitoneally with a strain of the infection. The only sign of disease in the goat itself was a positive group reaction with the Weil-Felix test. The goat had been

strain which was transferred first to a rabbit or mouse then to a human volunteer and finally to mice which became severely affected. The virus has been maintained by serial passage through mice for four years.

A number of persons received three doses of the vaccine before migrating to infected areas in the Far East—the presence of immune bodies in the sera of the immunized persons was shown by mouse-protection tests. One of 6 vaccinated persons who went to Sumatra had a slight symptom of dengue three months later—the others remained free from symptoms although a dengue "endemic" occurred among non-immunized persons. In New Guinea a number of non-immunized persons contracted typical dengue during three months of residence but none of the ten immunized was attacked.

The evidence of the production of a worthwhile immunity is not convincing

RABIES

JAUJOU L'Infection rabique en Corse au cours de l'année 1946. [Rabies in Corsica during 1946.] *Bull. de l'Ass. Méd. 1948* v. 132, Nos. 7-8, 128.

The epidemic of animal rabies described in this paper occurred in Corsica, from which the disease had been absent since 1872. Introduced by dogs accompanying soldiers, who had crossed from North Africa where rabies is endemic, the infection appeared first between April and October in 1944, reappeared in April 1945 and, after remaining latent for some months, flared up and spread rapidly until the end of 1946. All kind of livestock were involved in the epidemic, the infection of domestic animals having been largely due to the bites of foxes, among which the disease was extremely prevalent. The epidemic affected at least one-half of the island territory and losses among livestock were heavy. Diagnosis was established by histological examination and experimental animal inoculation of material recovered from domestic animals dead of the disease. The virus is stated to have been identical with the North African strain. Although the epidemic was confined to the animal population, 167 persons presented themselves for anti-rabies treatment—171 at the emergency treatment centre established at Ajaccio where phenolized vaccine was employed and 46 at continental Pasteur Institutes. No case of human rabies was reported, no ill effects of treatment occurred.

Measures of control included prophylactic vaccination of dogs and herbivorous animals, the restricted movement of dogs and the destruction of foxes by shooting, trapping or poisoned bait. Doubt is expressed as to whether the infection has actually been extinguished.

(An epizootic among foxes has troubled the South-Eastern States of the U.S.A. for some years.)

RIÉGOTON R., LAMY R., VIALAT C., BESSARD A. Contribution à l'étude de la rage. I. De la virulence de la rage fixe par voie sous-cutanée après addition de bave de chien normal. [RÉGOTON, LAMY & VIALAT.]

Contribution to the Study of Rabies. I. On the Virulence of Fixed Virus administered subcutaneously after the Addition of Healthy Dog's Saliva. *Amer. J. Hyg.* 1949 Mar v. 78 No. 3, 281-5. II. De la virulence de la rage fixe par voie sous-cutanée après addition de hyaluronidase. [RÉGOTON, BESSARD & VIALAT.] On the Virulence of Fixed Virus administered subcutaneously after the Addition of Hyaluronidase. *Ibid.* 285-6.

In the first of the articles under review the authors describe an experiment carried out with a view to determining whether or not the rôle played by it

saliva of a biting animal is purely a mechanical one. For the experiment, saliva was obtained from a healthy dog previously injected with pilocarpine and the fixed virus from the PASTEUR strain at its 1809th passage—a strain which had long lost its power of transmission by the subcutaneous route. To an emulsion of 1 : 10 by weight of this fixed virus was added an equal volume of saliva, the mixture being placed in the incubator for 1 hour at 22°C.

To each of 4 guineapigs 1 cc of the mixture was administered subcutaneously in the flank on 1st December 1948 and on the same date each of 4 control guineapigs received in the same region 1 cc of the mixture which, in this case, had not been kept in the incubator.

Of the first group, one developed typical paralysis on 9th December and was sacrificed, when at the point of death, on the 16th December. A second became paralysed on the 15th December and was sacrificed on the following day. The third and fourth animals escaped infection. Of the second group, none was affected. What factor was responsible for the alteration in behaviour of the fixed virus? In the authors' opinion it was an enzyme, not amylase (as proved by previous investigation), but probably hyaluronidase, their belief being based on the findings of DURAN REYNALS (*C R Soc Biol*, 1928, v 99, 6) and of HOFFMAN (*J Exper Med*, 1931, v 53, 43), who had some 20 years ago demonstrated the influence of that enzyme as a "spreading factor" on a number of viruses.

In the second article the authors describe how, using hyaluronidase obtained from testicular extract of the bull, they were able to effect a change in the behaviour of the fixed virus when injected subcutaneously into guineapigs identical to that obtained with the saliva of a healthy dog. Thus the belief expressed in their first article received strong support.

It is of interest to note that, in the guineapigs sacrificed in the first series of experiments histological examination of the neural axis showed not only lesions typical of fixed virus rabies but also, at the level of the neurones in the outer layer of Ammon's horn, nuclear lesions of a type unknown to the authors. There was frequent occurrence, in the same nucleus, of 2 nucleoli in every way comparable, but most marked was the presence, in nuclei still retaining their normal arrangement of chromatin, of oxyphilic bodies, like the nucleoli, varying in dimension up to the size of nucleoli and attached thereto in twos and threes. Such bodies, arranged symmetrically when small, tended to take up a position further from the nucleolus in proportion to their increase in size and to approach the inner coat of the nuclear membrane, a clear halo surrounding those of larger size. None of these formations was observed in the cytoplasm of the neurones. Similar findings were encountered in the second series of experiments.

LIEOU Y. C. Carriers of Rabies Virus. *Chinese Med. J.* 1948, Dec., v. 66, No 12, 694-9 [33 refs.]

The author defines a carrier of rabies virus as "one who, with all the external signs of good health bears, nevertheless in his organism a virus, detectable either by experimental inoculation or by microscopical examination". He divides carriers into four categories according to localization of virus, viz., in the brain, blood, saliva and subcutaneous tissues. The following paragraphs summarize his presentation of the subject—

Virus carried in the brain—Experimentally virus after intracerebral inoculation may be latent, unaltered and without causing symptoms for long periods (90-302 days respectively) in the brain of the fresh water turtle

Clinical observations made on 12 women, of from 15 to 48 years of age, revealed a continuous stimulation of the ovary both during and after anti-rabies treatment—a stimulation evidenced by marked irregularity of menstruation. It was found that the more the treatment was prolonged, the greater was the degree of disturbance—thus one woman treated over a period of 25 days twice experienced the menstrual flow during that time. The authors conclude therefore that anti-rabies treatment produces a disturbance of ovarian function.

ROANTREE W. B. *Surgical Treatment of Rabies.* (Memoranda.) *Brit. Med. J.* 1949 May 21 800

Complete destruction of rabies virus in wounds by cauterization alone is at best fortuitous and unlikely to occur in extensive deep or punctured wounds. The author, writing from Kolar Gold Field, India, quotes three fatal cases, in two of which cauterization had been employed—but he admits that the risk of rabies had been great. The patients had also had full, but somewhat delayed courses of anti-rabies vaccine.

He suggests that cauterization might well be combined with the modern surgical technique of excision of contaminated wounds—he briefly outlines such a treatment which consists principally of the following steps:

(1) Thorough cauterization immediately with concentrated nitric or pure carbolic acid.

(2) Careful sterilization of the skin over a wide area with pure rectified spirit and then with tincture of iodine.

(3) Surgical excision en bloc of all lacerated and potentially infected tissue. Dissection should be made in uncontaminated tissue planes with an ample barrier of clear tissue. A fresh knife is necessary for each wound, contaminated instruments should be kept rigidly separate and the tool with lyso, washed and sterilized at the earliest moment.

(4) The surgical wound is cauterized with the original cauterizing agent. After haemostasis is secured it is left unsutured and dressed.

Dr N. Veeraraghavan, Director of the Pasteur Institute, Coimbatore, pointed out to the author that in experimental animals, rabies occurs as quickly by inoculation of the sciatic nerve as of the subdural space. He raised the question of such inoculation of nerve trunks during surgical excision of the wound; the present author believes it to be likely that this could be avoided by immediate cauterization and careful avoidance of operative contamination.

He suggests that there is ground for testing this procedure experimentally. If it proved effective the method would be indicated in cases where (1) strong presumptive evidence of rabies infection was present, (2) wounds were amenable to radical excision, (3) adequate surgical facilities were available.

In more remote areas, cauterization alone would of course be necessary for local treatment—and in any case a full course of anti-rabies vaccine would be required.

WRIGHT, J. T., BELL, J. F. & HARVEY, R. Benzene-Ether Extracted Rabies Vaccine. *Science* 1949, July 30 118 19

Believing that their previous estimate of sharp separation of the rabies virus from tissue component had been largely frustrated by the presence of brain lipoids, the authors, as a initial step in the purification of rabies vaccine, attempted the preparation of vaccines by extracting these lipoids with aromatic solvents (acetone, benzene, carbon tetrachloride, diethyl ether). The technique followed may be thus summarized: The homogenized, infected,

brain tissue dried from a frozen state under vacuum the lipid solvents were added, the volumes in each case being about twice the wet volume of the original tissue suspension. After 2 hours in the cold room, the solvent was removed by centrifuging and decanting or by filtration, in either case the residue was resuspended in the solvent and at once recentrifuged or refiltered. Thereafter, with ether at -50°C , extraction was carried out in a similar way. The tissue was then freed from any residual ether by placing the container in a jar and exhausting by water suction.

Inasmuch as benzene extraction was found to provide the most potent antigen and proved to be least toxic to the rabies virus, further experimentation was undertaken, with the use of that solvent for extraction. Results of such experimentation went to show (1) Extraction with cold benzene and ether does not inactivate all the rabies virus in brain tissue but causes a marked reduction in the infective titre, (2) rabies vaccines, killed by preliminary ultraviolet irradiation and then extracted with benzene, suffer no loss of antigenicity, indeed they show, in most cases, a heightened antigenicity, and (3) rabies vaccines extracted according to the cold-benzene-ether method described above had much of their lipid content (41.5 per cent of the total dry weight) removed, thus eliminating "one of the major non-specific components of a very crude vaccine."

As a result of their experiments the authors conclude that, for the prevention of rabies benzene and ether-extracted vaccines may offer some advantage over unextracted vaccine

G Stuart

HABEL, K, BELL, J F & WRIGHT, J T **Benzene-Inactivated Rabies Vaccine**
Proc Soc Exper Biol & Med 1949 Mar, v 70, No 3, 455-7

In a previous article the authors [above] detailed a technique for the extraction, by benzene and ether, of infected, dry brain tissue containing rabies virus inactivated by ultraviolet light. Irradiation had then been employed for inactivation, because it was known to yield vaccines of high antigenic potency and because cold benzene and ether did not inactivate all of the virus.

In the present paper the authors describe a method for the inactivation of rabies virus by benzene alone during the course of extraction of brain tissue lipoids with that solvent. From experimental work it emerged that the virus contained in anti-rabies vaccines prepared from mouse and rabbit brain tissue could be wholly inactivated by exposure to benzene at 56°C for 12 hours and that the vaccines so treated showed no decrease in antigenic potency. Moreover, tests on mice and rabbits to determine the comparative antigenicity of benzene-inactivated and ultraviolet light-inactivated vaccines afforded proof that when there were differences, the benzene-inactivated vaccine in most instances showed the higher potency. From the above findings it may be concluded that inactivation of rabies virus by heating in benzene results in a highly potent vaccine and that the need for preliminary ultraviolet irradiation has been eliminated.

BELL, J F, WRIGHT, J T & HABEL, K **Rabies Vaccine freed of the Factor causing Allergic Encephalitis** *Proc Soc Exper Biol & Med* 1949, Mar, v 70, No 3, 457-61

The neuromyolytic accidents of anti-rabies treatment—post-vaccinal encephalomyelitis in man and its apparent counterpart, experimental allergic encephalitis in lower animals—are conditions which may occur when brain

tissue is injected parenterally. The aetiological agent concerned in the production of these accidents has long been sought and now as a result of the authors' successful search for an anti-rabies vaccine containing antigens of high potency, yet freed of the factor which causes allergic encephalitis in animals, the solution of the problem has been brought appreciably nearer. Such a vaccine was thought already to have been discovered when the authors at an earlier stage of their investigation had managed to remove the lipoids from the virus by treating the rabies-infected brain tissue with benzene and ether for at that time they believed that the removal of the lipoid components might also eliminate the material responsible for the paralysis. Experience showed, however, that their benzene-ether-extracted vaccine while suffering no reduction in antigenicity still retained its capability of producing paralysis in guinea-pigs.

In their efforts to remove from anti-rabies vaccine this paralysis-producing factor the authors had recourse to further experimentation during the course of which it emerged that after washing with M/10 calcium acetate solution followed by distilled water the virus antigen was precipitated from the vaccine without loss of its antigenic potency and such precipitate remained insoluble in water. The residual washed vaccine contained but 50 per cent. of the total nitrogen of the original vaccine and had a calcium content of 0.005 per cent. the factor causing allergic encephalomyelitis was present in the calcium acetate solution removed by filtration and could no longer be demonstrated in vaccines which had been previously treated with benzene and ether. Vaccines not previously so extracted were not freed of the factor causing paralysis when similarly washed with calcium acetate.

In view of the very great importance of the work described in the paper under review and of the possibilities which the findings hold out for the later employment in man of a wholly safe anti-rabies vaccine of high potency, it is considered desirable to quote the authors' summary of their paper —

"A method has been presented for the removal from rabies vaccine of the factor which causes allergic encephalomyelitis. This factor is not removed by extraction with benzene and ether but preliminary treatment of the vaccine with these solvents facilitate separation by subsequent treatment. The presence of calcium acetate prevents the loss of antigen when the vaccine is washed. It does not prevent removal of the encephalitic factor which appears to be water soluble. About one-half of the total nitrogen of the vaccine is removed by this washing process.

"The technique may be briefly summarized as follows —

(1) A suspension of infected brain in water is dried from the frozen state.
(2) The dried brain is extracted with benzene followed by ether (live virus may be killed in this stage by heating in benzene).

(3) After removal of the ether the dried brain is suspended in distilled water.

"(4) Sufficient solution of calcium acetate is added to make final concentration of M/10 calcium acetate and the suspension is permitted to stand in the cold for an hour or two.

"(5) The calcium acetate solution is removed by centrifugation or filtration and the sediment is resuspended in distilled water to the original volume with agitation (clumps of sediment must be broken up).

(6) The distilled water is removed by centrifugation or filtration.

"(7) The sediment is resuspended in distilled water or saline and homogenized. This is the washed vaccine.

KOPROWSKI, H *Experimental Studies on Rabies Virus* *Canadian J Pub Health* 1949, Feb, v 40, No 2, 60-67

It is agreed that one of the most effective measures of rabies control is the mass prophylactic vaccination of dogs but, militating against the successful application of such measures have been, in particular, the necessity for multiple vaccinations and the recorded occurrence of post-vaccinal neuroparalytic accidents. The studies described in the article under review were undertaken primarily with a view to discovering an efficient "single injection" method of canine immunization which, in practice, would be free from the risk of subsequent paralytic accident.

That the egg-adapted FLURY strain of rabies virus gave greatest promise for the development of a vaccine which would meet these requirements was confirmed and extended by the author's experimental work. Thus guineapigs inoculated extraneurally, although slightly susceptible to the low egg-passage levels of the strain, became almost completely refractory to the higher level passages, and only occasionally did one animal out of ten inoculated with 20 per cent suspension of infected embryos show any signs of paralysis. Conversely, the immunity response of the surviving guineapigs, later challenged with street virus, was highly satisfactory.

Further repeated experiments adduced abundant proof that the FLURY strain given parenterally is innocuous for the canine species. Thus dogs, which received the intramasseter inoculation of a 20 per cent embryo suspension, survived the 12 months' observation period without having shown any sign of illness. Similarly animals which had been inoculated in the muscles of the hind legs with 5 cc of a 20 per cent suspension of the virus, or by the intramasseter route with a 40 per cent embryo suspension remained without ill-effect during the entire periods of their observation (2 to 6 months).

Encouraged by these results, the author then attempted a determination of the immunizing power of the FLURY strain in dogs. Animals were vaccinated in the muscles of the hind legs with a single 5 cc injection of either fresh or lyophilized preparations consisting of either a 20 per cent or 40 per cent suspension of infected chick embryos at various egg-passage levels and then challenged, at different intervals, varying from 5 to 27 weeks, by bilateral intramasseter inoculation with a 10 per cent suspension of street virus giving mouse-intracerebral LD 50 titres of $10^{-4.50}$ to $10^{-6.15}$. Of 66 dogs vaccinated, only 2 succumbed to the massive test inoculation, whereas 23 of the 37 control dogs died. Duration of such immunity in dogs is now under study.

Turning to the protection of human beings against rabies and the development of a procedure which would be as effective as the PASTEUR treatment but would not carry with it the danger of neuroparalytic accident, the author suggests the substitution of anti-rabies serum for the vaccines now in use. Experiments on the protective power of the serum (a concentrate of the beta- and gamma-globulin-containing fractions of pooled rabbit plasma fractionated by sodium sulphate precipitation) were carried out on hamsters along lines corresponding to those encountered in nature, i.e. first infection with street virus, followed by treatment, the remarkable protective value of one injection of antiserum, as contrasted with the lack of value even after full courses of phenolized vaccines in massive dosage or of living virus vaccines, was clearly demonstrated. Factors found to influence the action of the serum included its degree of dilution, the amount of virus present in the infecting inoculum and the time-interval between infection and treatment.

In the author's opinion, "the general evidence in favour of serum treatment is so conclusive, especially as the danger of neuroparalytic accidents following

serum treatment does not exist that a thorough field trial of serum prophylaxis in rabies is fully warranted."

BÉQUIGNON J. R. & VIALAT C. Les vaccinations antirabiques à l'Institut Pasteur en 1947 [Anti-Rabies Vaccinations at the Pasteur Institute in 1947] *Ann. I. st. Pasteur* 1948, Aug., v. 75 No. 2, 163-7

This Report details the procedure followed at the Pasteur Institute of Paris in the treatment of persons exposed to the risk of rabies infection and provides statistics for the year 1947. During that year 71 bitten persons received treatment, no rabies death occurred and no neuromuscular accident followed treatment. Animals incriminated in the biting of the persons treated were 175 dogs, 23 cats and 8 rats. These animals included 1 in category A (proved rabid experimentally), 3 in category B (diagnosed rabid clinically) and 208 in category C (suspect only). It is noted that 1947 was the 23rd successive year in which no rabies death occurred among persons treated at the Institute.

Of the 54,990 persons treated during the 62 years period 1886-1947 there were 7,083 bitten by animals in category A, 27,190 by animals in category B and 20,717 by animals in category C. 151 died of rabies thus providing a percentage mortality of 0.28.

PLAGUE

BERNARD L. DOUVET G. & JAUJOU Une épidémie de peste bubonique à Ajaccio (1915) [An Epidemic of Bubonic Plague at Ajaccio (1915)]. *Rev. Trans. Inst. Nat. Hyg. Paris* 1948 v. 33, 5-16 figs

In this outbreak 13 persons were attacked within a period of 10 weeks in the months May, June and July 1915. The disease had not been known to occur in the Island of Corsica within living memory so the infection must have been introduced by the sea route.

Reference is made to the finding of dead rats before the outbreak but these were not examined. All the 148 rats trapped afterwards were found free from infection of these 14 were *Rattus rattus alexandrinus* and the rest were *R. norvegicus*. On the 148 rats only 101 fleas were found, 47 of these were *Xenopsylla cheopis* of which all but 8 were found on the 14 specimens of *R. rattus*.

The outbreak was confined to three small areas one of which was military barracks. All the usual measures of control were very thoroughly carried out, including the compulsory vaccination of all the 35,000 inhabitants of Ajaccio. The complete disappearance of the disease was attributed partly to the scarcity of the vector fleas and partly to the measures of control that were adopted.

TEJAN Y. T. Culture de *Pasteurella pestis* à partir d'un seul microorganisme
Cultivation of *P. pestis* starting from a single cell. *Univ. Soc. Path. E. et. Afr.* 1949 42, Nov. 34 89-91

Using a micromanipulator the author has succeeded in isolating single cells of *P. pestis* on ten occasions from a suspension of the organisms maintained in peptone water for four hours at a temperature of 34°C. 1-3 three coves a single cell gave rise to cultures on peptone agar. For details of the technique the original paper must be consulted.

The cultures have been made over to G Girard who proposes to study them from the point of view of obtaining living attenuated vaccines originating from single cells, the original culture used by the author was of an avirulent strain

John W D Megaw

DEVIGNAT, R La prophylaxie de la peste au Lac Albert par l'association de la dératisation et de la vaccination (virus-vaccin E V de Girard et Robic) [Plague Prevention in the Lake Albert Region by Rat Destruction combined with Vaccination with the Girard-Robic Vaccine] *Bull Soc Path Exot* 1949, v 42, Nos 1/2, 43-52, 1 graph

This paper deals with plague prevention as practised during the years 1937-46 in a zone of 100 by 40 kilometres on the west shore of Lake Albert on the borders of the Belgian Congo

Every month a gang of rat catchers visits each occupied hut in the zone and seeks out the nests of the rats The result has been an apparent increase in the rat population, the average number found in each hut was less than one in 1937-38 and it now ranges from 2.1 to 2.5 The average number of fleas found on each rat has, however, been considerably reduced—to about one-third of the previous figure

During 1939 and 1940 the rat-flea population was at its lowest, yet these were the years of highest prevalence of plague

The rat-catching campaign was maintained as a means of detecting the presence of infection, pooled suspensions of femoral bone marrow of all the rats caught in each village were inoculated into guinea-pigs and when infection was detected the villagers were inoculated with the Girard-Robic living avirulent vaccine [See this *Bulletin*, 1939, v 36, 314]

During the whole period about 400,000 doses of vaccine were given, and the author is satisfied that it was highly effective, there were only 16 cases of plague among the vaccinated against 116 among [an unstated number of] unvaccinated persons The earliest attack in a vaccinated person occurred three months after vaccination

An increase in virulence of the living vaccine occurred on one occasion, but the virulence was reduced to the former low level by passing a stream of air through a solution of caustic potash and then through broth cultures of the strain This process was continued for eight days, it had already been found effective in reducing the virulence of three local strains of fully virulent *P pestis*

John W D Megaw

DAVIS D H S Current Methods of controlling Rodents and Fleas in the Campaign against Bubonic Plague and Murine Typhus *J Roy San Inst* 1949, May, v 69 No 3 170-75

A useful survey of present methods

GRATCH, I, PURLIA, P L & MARTIN, M L Effect of Sodium Fluoroacetate (1080) in Poisoned Rats on Plague Diagnosis Procedures Preliminary Report *Pub Health Rep Wash* 1949, Mar 18, v 64, No 11, 339-42

By fully controlled experiments the authors have found that rats poisoned with sodium fluoroacetate are just as suitable for bacteriological examination to detect the presence of plague infection as are rats caught by trapping or poisoned by hydrocyanic acid gas

As ordinarily used the fluoroacetate does not reach the liver of the rat in quantity sufficient to damage guinea-pigs inoculated with suspensions of the

liver and it has no adverse effect on the viability of *Pasteurella pestis* contained in the tissues of infected guinea-pigs.

In vitro the poison was found remarkably free from bacteriostatic effect on cultures of *P. pestis*.

John W. D. Megaw

SERGEANT Ed & SERGEANT Et. Nouveau procédé de dératisation basé sur l'emploi du DDT [A New Method of Rat Destruction by DDT] *Arch. Inst. Pasteur d'Algérie* 1949 Mar v 27 No 1 18-30 1 fig. [Refs. in footnotes.]

A powder containing 80 per cent. DDT deposited in and round the entrances of rat holes has been found to kill within a few days about 80 per cent. of the rats. The powder is left permanently to ensure cumulative action of the poison.

No details of the quantity applied are given except for the statement that the powder is used in the same way as for the destruction of cockroaches. For mice a 5.0 per cent. powder is said to be effective.

Although the powder is not highly toxic for man and domestic animals precautions are recommended against the risk of contamination of foodstuff and of contact with domestic animals especially cats.

CHOLERA

DE MOOR, C. E. Paracholera (El Tor): Enteritis Choleraformis El Tor van Legeren. *Bull. World Health Organization* Geneva 1949 Mar 2, v 1 5-17 2 maps. [Refs. in footnotes.]

Following on earlier reports on choleraform disease in Celebes attributed to a haemolytic vibrio (this *Bullet.* 1939 v 38 374) another account of investigations on the subject is given with a discussion of its epidemiological significance. The questions are raised (1) whether the haemolytic vibrio of Celebes and the *El Tor* are identical, (2) whether the disease in the Celebes is distinguishable from cholera, and (3) whether quarantine regulations should be applied against cases and carriers from which the *El Tor* type of vibrio is isolated.

The Celebes cases were not distinguishable clinically from Asiatic cholera and the mortality varied from 69 to 73 per cent.

Bacteriology.—Strains of the haemolytic vibrio were examined which had been isolated from 370 sources in the Celebes including patients, contact and other healthy persons and from wells both in the vicinity of cases and in areas where the choleraic condition had not occurred. All strains were serologically identical with *V. cholerae* and the *El Tor* vibrio by the usual agglutination tests.

water was added to a 1 in 200 dilution of cholera-O serum in 0.3 per cent. Na_2CO_3 , H_2O it promptly agglutinated a suspension of *V. cholerae* similarly treated remained unaffected. A thick suspension of *V. cholerae* in 0.5 per cent. NaHCO_3 was completely precipitated when treated with an equal volume of a 0.5 per cent. solution of HgCl_2 but a suspension of the *El Tor* vibrio remained stable.

A study of the haemolytic action of the Celebes and *El Tor* vibrios showed the following to be characteristics of newly isolated strains: (1) haemolysis in blood broth within 4 hours growth; (2) positive Coagulase test with both cultures and (3) beta haemolysis on anaerobically incubated blood agar. Greg's test

was usually positive with broth cultures 12-hours old, the haemolysis being strongest with cultures 2-days old, but cultures 4-days old were no longer haemolytic. In the refrigerator a broth culture retained its haemolytic power for weeks. Cholera strains were found to show only slight haemolysis in blood broth cultures and at the earliest after 48 hours growth. Greig's test was always negative. On blood-agar, only digestion of blood-pigment was visible.

The test for acetylmethylcarbinol by Barritt's method was not fully differential.

No difference in behaviour was demonstrated between the vibrio of Celebes and that of El Tor.

The epidemics The first outbreak described consisted of 48 cases distributed over a period of eight months from September, 1937, to April, 1938, with a very scattered distribution. The second series occurred between October, 1939, and April, 1940, and included 37 cases within a radius of 20 km. around Lake Tempe and 26 cases divided between two areas of the East Coast. The third series consisted of 7 cases in 1946 which were also widely scattered. The total recorded from September, 1937 to December, 1944, was 118 cases in 70 *kampongs*. There was no seasonal incidence, cases occurring both in an extremely dry season and in a wet season of the year. Cases were sporadic and there was no tendency to spread to large centres of population in spite of extensive road traffic. In view of the very low and scattered incidence and the absence of epidemic tendency the mass inoculation and isolation measures which were at first applied were later omitted.

Incidence of the vibrio The vibrio was isolated from the stools of 10 per cent of 579 family contacts examined, and from 42 per cent of the 132 wells used by patients. Half of the family contacts examined continued to excrete the vibrio after one week but, with one exception, they became permanently negative after 11 days. The vibrio was recovered intermittently from the exceptional case up to 27 days. The examination of 5,566 healthy persons in the infected area who were not family contacts resulted in the vibrio being isolated from 21 (0.4 per cent). The organism was also isolated from 43 out of 1,023 wells (4 per cent) in *kampongs* in these areas. In *kampongs* where cases had actually occurred it was isolated from 0.9 per cent of 1,225 healthy persons and 6 per cent of 172 wells. In uninfected areas, and even where the disease had never been noted, the vibrio was occasionally found.

Epidemiological considerations The opinion is expressed that the El Tor vibrio is an accidental resident in water but does not thrive there. The author considers infection of wells and rivers with the El Tor vibrio to be of human origin and that the vibrio is maintained by successive groups of persons becoming temporary carriers, chronic carriers are not found. Vibrios in wells act as indicators of human infection.

The sporadic and static character and the low mortality of the disease attributed to the El Tor vibrio are in striking contrast with the epidemic nature of cholera with its tendency to spread and its high morbidity. After an epidemic the cholera vibrio disappears from the community while the El Tor vibrio may remain in an area for prolonged periods and may even be found where no cases of choleraform disease have occurred.

Occasional pathogenicity, static character, sporadic occurrence, and slight morbidity explain why the El Tor disease has not been encountered during the Mecca pilgrimage and in countries around the Red Sea (Hejaz, Egypt and Iraq) and in Bengal and Madras where the true El Tor vibrio has been found in healthy persons or in wells.

The El Tor disease is a commensal infection and is sporadically of endemic nature while cholera is a parasitic infection and is endemic. It is suggested the disease caused by the El Tor vibrio should be designated "paracholera El Tor."

Quarantine strict isolation of sick persons disinfection and mass immunization are not justified in the case of paracholera because this disease does not spread epidemically and claims in the long run few victims. However so long as there is no general agreement on the identification of the El Tor vibrio a paragraph will be necessary in any international quarantine convention on cholera, regulating the official notification of cases of paracholera (El Tor) and of carriers of the El Tor vibrio." Van Loghem is quoted as stating that "If the difference in kind between *V. cholerae* and *V. bius* El Tor is recognized there is no question of cholera asiatica but of an El Tor disease. He proposed the term enteritis choleraiformis El Tor."

[The observations presented support the usual practice of not applying quarantine measures when the El Tor vibrio is isolated. It can readily be differentiated from *V. cholerae* to which alone quarantine regulations will apply and it would hardly be necessary to make special regulations in regard to it.]

J Taylor

VEERARAGHAVAN \ A Simple Medium for Cultivation of *V. cholerae*. [Correspondence] *Nature* 1949 Jan. 22, 138.

Heavy growth of *V. cholerae* was obtained in a liquid medium consisting of a salt mixture with L-cystine glucose and "Marmite" at initial pH of 8.8 when alkalinity was maintained by the periodical addition of sodium bicarbonate and small quantities of glucose added at the same time. Ammonium sulphate was included in the salt mixture and without it growth ceased at the end of 10 hours. When sodium bicarbonate and glucose were added 1, 10, 18 and 24 hours from the beginning of incubation and the pH raised to the vicinity of 8.0 the concentration of vibrios in the culture reached 12,000 to 14,000 million at the end of 30 hours.

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

CORLEO E. Rectal Swab in the Investigation of Diarrhoea in Children. *Indian J Med Sci* 1949 Apr v 3 No. 4 266-71

The apparatus required for preparation of rectal swabs consists of a proctoscope glass slides and cover slips, normal saline, iodine solution soft paraffin and "broom sticks" to which the cotton swabs are attached. The results of examination of rectal swabs in 229 acute and 74 chronic cases of diarrhoea demonstrate that the rectal swab provides a sample of the rectal contents adequate to discover all the abnormal findings normally found on faeces examination.

A second table in a comparison between rectal swab and stool examination in 59 patients shows that a percentage of acute diarrhoeas in children is due to a bacillary infection. The figures for macrophage cells are nearly equal while for pus cells the sample from the rectal swab is definitely better moreover it gives a positive result for *E. histolytica* more often particularly for the active trophozoites and it is also better for the detection of *G. duodenalis* ova. A search through voided stools is more profitable for finding round worm ova. In "normal" patients the rectal swab detected more with *Gardia* and cysts of *E. histolytica*. In 15 out of 30 patients the rectal swabs failed to reveal anything but there were only eight negative results with stool examination.

The rôle of giardiasis in acute and chronic diarrhoeas of children is important. Out of 310 acute diarrhoeas 16.4 per cent were due to this infection, as were 43 per cent of 130 chronic diarrhoeas. The youngest child in whom *Giardia* was found was 14 days old.

P Manson-Bahr

REDDY, D G & THANGAVELU, M. Some Aspects of Amoebiasis in Madras. *Indian Med Gaz* 1948, Dec., v 83, No 12, 557-63, 6 figs on 2 pls [25 refs]

An analysis of 2,641 cases treated in the General Hospital, Madras, is as follows —

Dysentery	Total number of cases	Percentage of incidence	Number of deaths	Percentage of deaths
Amoebic	1 011	38.3	62	6.13
Bacillary	1 345	50.9	134	9.9
Mixed	28	1.1	1	3.8
Non specific	257	9.7	47	14.4

In children the incidence of amoebic infection is low. This is well brought out by figures shown in a table. Males are infected more frequently than females. Amoebiasis in general does not exhibit that seasonal incidence which is so characteristic of bacillary dysentery. In 44 postmortem examinations intestinal lesions were found in 38 and hepatic lesions only were seen in the remaining six. In most cases, the primary lesion begins in the caecal area, but with the progress of the disease the entire colon seems to become involved. In only two cases was amoebic involvement of the appendix observed, but the rectum is frequently affected. Amoebic granuloma was occasionally seen. An account of six such cases has already been published [*this Bulletin*, 1947, v 44, 583]. Amoebic ulceration may co-exist with typhoid.

From 1941 to 1946 1,534 cases of hepatitis were treated in the Government Hospital, Madras, and of these 364 (30 per cent) were diagnosed as being of amoebic origin, during the same period 84 cases of liver abscess were treated in the surgical wards of the General Hospital and 40 in the King George Hospital, Vizagapatam. The largest number fall under the age group of 20 to 50 years, and the incidence of liver abscess among Hindus is about twenty times that in Muslims. Males are much more commonly affected with liver abscess than females.

In six out of 15 cases of liver abscess specially investigated at autopsy there was no evidence of recent intestinal lesions. Multiple abscesses were present in 3 of 15 cases.

Deep jaundice of an obstructive type is a very rare accompaniment of amoebic abscess of the liver and an instance of this is recorded, where an encysted liver abscess caused an obstruction of a main bile duct and eventually produced biliary cirrhosis.

Encysted liver abscess may be mistaken for a solitary gumma. Rupture into the pericardium is very rare and occurs in abscess of the left lobe where it may be mistaken for tuberculous pericarditis or other pericardial effusions. One such instance is recorded. A case is also described where the abscess contents entered the rectus sheath.

The authors discuss pulmonary amoebiasis, amoebic abscess of the brain and cutaneous amoebiasis and quote cases from the experience of other workers. None of these conditions is recorded in their own series.

P Manson-Bahr

SEN V. C. Amoebic Vaginitis. *Brit. Med. J.* 1949 May 7 808.

Amoebic vaginitis is rare and the author refers briefly to the available literature [see this *Bulletin* 1944 v 41 44 133 1945 v 42 38 1946 v 43 42]. He then reports the case of a Nepalese woman of 33 complaining of a profuse seropurulent vaginal discharge with some soreness in the vulva and vagina and a burning sensation during micturition. The discharge was almost continuous and unrelated to menstruation.

The discharge had been present for some 4 to 5 months about one month before it was noticed the patient had had a severe attack of dysentery (presumably amoebic) for which non-specific treatment had been given elsewhere.

Pelvic examination showed slight swelling of the right labium, the cervix and the uterus, which was soft and anteverted. There was a small ulcer in the fourchette many linear ulcers lying mostly transversely in the mucosa of the vagina, and extensive ulceration of the cervix. The ulcers were punched-out with overhanging edges and raw bases.

Many active forms of *Entamoeba histolytica* were found in smears of the vaginal discharge from scrapings of the ulcers and from the discharge obtained by milking the urethra. Cysts of *E. histolytica* were found in the stools, but no ulcers were found in the lower ano-rectal canal. The liver was enlarged and tender and the descending and iliac colon was thickened.

Emetine (1 grain daily intramuscularly) was given to a total of 1 gram (in 15 days) together with local saline douches. After five days, discharge and discomfort were relieved, the ulcers were almost healed and the cervix was returning to normal. A few round and sluggish forms of *E. histolytica* were found in the aspirated cervical discharge similar forms were found in a catheter specimen of urine. A local treatment was given for an accompanying cystitis but emetine was continued, followed at night by stovarsol vaginal compound and an alkaline mixture.

The ulcers healed completely in two weeks, the symptoms and discharges disappeared and the patient felt quite well.

The diagnosis of amoebic vaginitis is based on the presence of the vegetative forms of *E. histolytica* in the discharges and the ulcers, the response to amoebicidal drugs and the morphological character of the ulcers.

The author suggests that infection of the vagina is by continuity with the recto-rectal canal, the method of ablation after defaecation as practised in Bengal would no doubt help mechanically. The uterus is often enlarged and it may well be infected in some cases also. It is suggested that leucorrhoea due to *E. histolytica* may be fairly common in India and should be constantly borne in mind.

VAN STEEN P. B. Naak te opmerkingen over de behandeling van amoebien dysenterie en amoebiasis. [Observations on the Treatment of Amoebic Dysentery and Amoebiasis. *Nederl. T. Genees.* 1947 Jan 8 v 83 (4) 105-11. English summary (5 lines).]

A brief review and discussion of the drugs used.

EL-CHAMRY A. A. Th. Combined Use of Salvarsan and Diiodoquin in the Treatment of Amoebic Infections of the Intestine. *J. A. Egypt. Med. Ass.* 43 1949 J. 1-5.

The theme of this paper is based on the belief that bacterial infection of the intestines is an important contributory factor to the pathology of amoebiasis.

On this basis, sulphasuxidine and diodoquin were given to 36 patients with acute and 50 with chronic amoebic dysentery

The first group manifested the usual symptoms, frequent blood and mucus stools, tenesmus and colic. The symptoms associated with the second group were varied and included a variety of obscure abdominal pains and discomforts. The faeces usually contained *E histolytica* cysts. Sulphasuxidine was given in doses of 3-4 tablets (0.5 gm each) three times daily for 15 days, and diodoquin, 3 tablets (0.21 gm each) three times daily for 20 days. The anti-amoebic drug was given simultaneously with the anti-bacterial drug so as to enable it to exercise its inhibitory effect on the bacteria.

The patients with acute infections responded rapidly. No relapses have yet been reported though the first patient received treatment seven months previously. Results in chronic cases were variable. Improvement was marked in half of them. A few who relapsed quickly responded when treatment was resumed. Some in whom improvement was not very satisfactory received another course 2-3 weeks later "with better result". Pruritus ani occurred in a few cases and Paramibe, a preparation of the same chemical constitution as diodoquin was substituted. No untoward effects were observed.

CROSNIER, R, BERNIER, G, MOLINIER, A, BESSEIGE, H & LEFEBVRE, P
Prééminance thérapeutique de la conessine dans l'amibiase aiguë [High
Therapeutic Value of Conessine in Acute Amoebiasis] *Bull et Mém Soc
Méd Hôpité de Paris* 1949, Nos 9/10, 386-92

The authors advocate a gross dosage of 5 gm to 6 gm of conessine, given by mouth, according to the tolerance of the patient, they stress the fact that under no circumstances must the daily dosage exceed 0.5 gm, the daily dosage is decreased as treatment progresses over a period of two weeks. Adjuvant treatment consisted of the administration of calcium gluconate in 1 gm doses intravenously daily, gardenal was given as necessary, and a salt of quinine was also given "as a general tonic, to neutralize the nervous phenomena, and as an antimalarial".

Conessine can be given with impunity when there are signs of emetine poisoning, emetine-resistant infections are susceptible to it, there are no contra-indications to its use, as it causes no serious toxic action, but it should always be given under close medical supervision, the recommended course of treatment must strictly be adhered to. Conessine can be given intramuscularly in doses of 0.1 gm, the injections are painless owing to the local anaesthetic properties of the drug but there is local necrosis, while intramuscular injection is not advised it may be resorted to in cases of alimentary intolerance.

One hundred and twenty-eight cases of intestinal amoebiasis were treated with conessine, 12 of them were cyst-passers. One hundred and fifteen (68 per cent) of these were cured of their infections. The "cure" was consolidated in most cases by a repetition of the course, but of the 44 patients re-treated 9 were found still to be infected and another 3 subsequently suffered attacks of acute amoebic dysentery. It is concluded that the treatment gave a cure rate of 89 per cent. Nineteen cases of amoebic hepatitis were treated, apparently with satisfactory results, with conessine.

Various suggestions are made on further lines of investigation of the action of conessine in amoebiasis, which the authors state to be equal or superior, to emetine.

SIGUIER F., CROSTIER J. & SAPIE JALOTIERE, IL. Amibiase hépatique sural-cite probable. Ecbec d traitement mixte émetine-cosamine-penicilline. Guérison par l'association émetine-streptomycine [Probable Secondary Infection in a Case of Hepatic Amoebiasis. Failure to respond with Combined Emetine-Cosamine-Penicillin Treatment and Cure with Emetine combined with Streptomycin.] *Bull. d'Urm. Soc. Méd. Hôpit. de Paris* 1949 No. 13 11 620-24 3 figs.

MANSON BARR P. The Treatment of Amoebic Liver Abscess with Chloroquine. *J Trop Med & Hyg* 1949 May v 5 No. 5 91 3 1 chart. [10 refs.]

While emetine combined with emetine bismuth iodide is usually effective in the treatment of hepatic amoebiasis there is a residue of cases of liver abscess in which these drugs fail to act.

The author refers to the use of chloroquine in hepatic amoebiasis and suggests that it probably acts by concentration in the liver parenchyma [for experimental observations on animals regarding relative concentrations of emetine in the liver and intestine see this *Bulletin* 1948, v 45 1004].

The history and pharmacology of chloroquine and related substances are discussed and reference is made to two published accounts of its use in hepatic amoebiasis. COVAX this *Bullet* 1948 v 45 490 reported rapid disappearance of clinical manifestations in six cases of hepatic amoebiasis but a persistence of *E. histolytica* in the stools of 13 out of 23 patients having intestinal amoebiasis after treatment with chloroquine as the drug is almost entirely absorbed from the gastro-intestinal tract its effect on intestinal amoeba is attributed to plasma or tissue concentration.

MURRAYROD and KENT demonstrated a case at a Laboratory Meeting of the Royal Society of Tropical Medicine and Hygiene (*Trans Roy Soc Trop Med & Hyg.* 1948 42, 15) in which trophozoites of *E. histolytica* were present in the liver pus, but were resistant to emetine. On the fifth day of treatment with chloroquine (0.25 gm. three daily by mouth for 18 days) the amoebae disappeared and by the twelfth day the abscess cavity had healed. The patient was well enough to be discharged from hospital two weeks after completion of the course and was prescribed a maintenance dose of 0.5 gm. chloroquine twice a week for 3 months (in this case the discharging liver abscess had been opened 4 months before and had also resisted treatment with penicillin and streptomycin given to deal with secondary infections present).

In the case under review the present author treated a European patient suffering from an advanced amoebic abscess of the liver who had been interned in Siam for 3½ years. He had no history of amoebiasis but in 1948, two years after he returned to Calcutta, symptoms of this condition began. Clinical and radiological evidence suggested that he had subacute hepatitis complicated with early pulmonary tuberculosis. He was given a course of streptomycin with no apparent effect on his pyrexia. Later he became worse and the manifestations of amoebic abscess of the liver became evident. In October 1948, in Madras, he was given emetine and penicillin and 1½ pints of amoebic pus were removed from his liver. On arrival in Britain he was extremely ill and the evidence of liver abscess was still marked. No amoebic cysts were found in the stools.

There was no adequate response to emetine followed by emetine bismuth iodide. Chloroquine was then given and the temperature chart (reproduced in the paper) showed an almost immediate response. The temperature became normal and the signs less apparent. However pyrexia began again some 10 days later but yielded to renewed chloroquine therapy. Pyrexia was then uninterrupted and the patient is now in good health.

The first course of chloroquine diphosphate consisted of 4 gm over eight days and the second of 4.75 gm over 16 days. The priming dose was 0.75 gm (0.45 gm base) followed by a sustained dose of 0.3 gm daily and later 0.5 gm (0.3 gm base) daily. No toxic effects were observed. Half the amount of chloroquine appeared to be equally effective in controlling the fever during the second course.

LEPROSY

SEN, P. **Leprosy in Calcutta** *Internat Med Abstracts & Reviews* Calcutta 1949, Jan, v 5, No 1, 20-23

This note gives data regarding the incidence of leprosy in Calcutta as compared with adjacent districts, and discusses the suitability of the city for the proposed all-India Leprosy Institute. Surveys of the disease in cross sections of the Calcutta population showed that the incidence varied between 0.3 and 1.65 per cent with an estimated rate of 0.5 per cent, or 20,000 in a population of 40 lakhs (4 millions) including the suburbs. Work in the four Calcutta clinics showed over 10,000 leprosy patients as permanent residents, some Calcutta dermatologists consider this to be an underestimate. A table shows the estimated number of leprosy cases and the rate per thousand population in the districts of Western Bengal, which are all higher than in Calcutta, but the author thinks that the greater density of cases makes them more dangerous in Calcutta. In the latter part of the paper he advocates Calcutta as the best site for the all-India Leprosy Institute on account of the laboratory and other medical facilities and a leprosy hospital with nearly 200 beds for permanent patients. [This opinion ignores the great advantages of an agricultural colony with ample land for cultivation and for housing far larger numbers of cases than Calcutta can provide for, with greater facilities for testing new drugs on in-patients under close observation.]

TISSEUIL, J. **Sur 3 inoculations positives de la lèpre humaine au rat d'élevage** [Successful Inoculation of Human Leprosy into Rats] *Bull Soc Path Exot* 1948, v 41, Nos 11/12, 649-52

The author has in three instances, out of a number, succeeded in inoculating human leprosy into rats. In the first positive experiment, an emulsion of leproma from an Argentine patient was injected into the testis of 20 rats. A small yellow lump in the testis of one of them was grafted under the skin of another rat and produced a nodule, sections of which showed very numerous bacilli. Passages into the testicles of three other rats were negative. In the second experiment, ten rats were injected with suspensions of lepromata and the surviving rats were re-inoculated from a leproma five months later and after six more weeks a nodule with a caseous centre was inoculated into each flank of another rat, which resulted in a nodule very rich in bacilli, and further passages of the bacilli were obtained. In the third positive experiment, 10 rats were placed in an hermetically sealed chamber contaminated by pulverized lepromata and one of the rats killed 15 months later showed miliary nodules and a little caseous material in the lungs rich in bacilli, which could not be cultivated on Löwenstein's medium. Inoculation into a guinea pig caused a general infection free from evidence of tuberculosis. Five rats inoculated at the same time were killed eight months later and all of them showed gross lepromata at the site of inoculation.

The author then discusses criticisms of his work, especially the occurrence of spontaneous rat leprosy and without under-estimating them he considers it was useful to record his experiments to help others with regard to such inoculations.

LIANG Sadie & CHOW G. H. The Blood Picture in Leprosy. *Amer J M I Sci* 1949 Mar v 17 No. 3 268-70. (13 refs.)

Previous literature shows differences of opinion regarding the blood changes in leprosy, so the authors, in China, have carried out estimations in 98 cases which had not recently been under treatment. Those showing helminthic infection were treated before the blood was examined. The authors did not find that promin treatment had much effect on the blood except in causing some reduction in the haemoglobin but the red and white corpuscle counts were little affected by the drugs used. Both lepromatous and neural cases are included, but patients with intercurrent diseases were excluded. The results are shown in tables and include the following data. Wright's stain and the Wintrobe haemocrit were used and the results are compared with the standard figures of Wintrobe and with those of Chinese workers, which do not deviate much from the general average. Anaemia was rather constant but in no case severe. Macrocytic and normocytic anaemias were met. Reticulocyte counts were distinctly low and they varied between 0- and 0.9 per cent. This the authors are unable to account for. The sedimentation rate was raised in all but four and averaged 18 mm. Leucocytosis of a moderate degree was present in 10 or 27.7 per cent chiefly in advanced lepromatous cases. Only two showed moderate leucopenia. The neutrophil count was definitely deviated to the left but this is usual in the Chinese so it is not significant. High eosinophil counts were a notable feature even when the stools had become negative as regard helminths, so they consider this related to the disease especially in its lepromatous form in which type it chiefly occurred. Monocytosis and lymphocytosis showed a high incidence with 19 cases or 5.2 per cent of each, which is not surprising in such a chronic disease as leprosy. During their two years work there was no clinically marked flare-up or deterioration resulting from treatment among the severe cases. Neither lymphocytosis nor monocytosis appeared to have any prognostic value but the authors agree with other workers that they may be useful indicators of the presence of leprosy. L. Rogers

DHARMENDRA. A Note on the Histopathology of Leprosy. *Internal M J Abstracts & Review* Calcutta. 1949 Jan v 8, No. 1 5-8.

FLOCH H. & CAMAIX R. Aspects histopathologiques de la Lèpre en Guyane française. *Histopathological Aspects of Leprosy in French Guiana*. *Istitut Pasteur de l'Amérique du Nord et de l'Inde*. Publication N° 176 1949 July 7 pp.

The authors in French Guiana carried out work during one and half years on the histology of leprosy including the effects of sulphone treatment. In the first place they agree that the histological changes in different (or intermediate) uncharacteristic cases this *Bullet* 1947 41 153. In leucoid and lepromatous cases the histological picture is different. They agree with the observations of FRIED and CHAMBERLAIN concerning the histological changes in cases improving under sulphone treatment. The histological picture follows the points. In lepromatous cases under sulphone treatment, there are changes of cutaneous epithelium and there are IL accumulated. There are few numerous infiltrations. The lymphocytes are seen and the plasma cells

diminish in numbers. With the atrophy of the nodules, connective tissue cells predominate. On the contrary, in "indifferent" and tuberculoid forms the histological appearances are not affected by sulphones.

Sections are better for determining the changes in the number and appearances of the lepra bacilli than are teased specimens. The examination of at least four sections is recommended. By this method the percentage of bacteriologically positive cases is raised to 31 of "indifferent" and to 29 in tuberculoid minor and to 88 in reacting tuberculoids, so that in tuberculoid cases when examined in stained sections the organisms are more frequently found than by former methods. Under sulphone treatment the lepra bacilli become much decreased in numbers, show morphological changes and do not stain as well, especially those in the neighbourhood of blood vessels. This, the authors think, explains the resistance of "indifferent" and tuberculoid cases to sulphones, because in these forms there is less vascularity and many of the organisms are protected from the action of the drugs by being situated in nerve trunks, which the sulphones reach with difficulty. *L. Rogers*

COCHRANE, R. G. Some Brief Comments on the Classification of Leprosy. *Internat Med Abstracts & Reviews* Calcutta 1949, Jan, v 5, No 1, 2-5

COCHRANE, R. G., RAMANUJAM, K., PAUL, H. & RUSSELL, D. Two-and-a-Half Years' Experimental Work on the Sulphone Group of Drugs. *Leprosy Review* 1949, Jan-Apr, v 20, Nos 1/2, 4-64, 15 figs & 1 chart [14 refs]

This long paper records brief notes on 54 cases of leprosy treated by sulphones in South India in the course of two and a half years. Most of them were given diasone or sulphetrone orally with very similar results to those recorded previously by a number of leprologists. Of greater interest are six cases given injections of sulphetrone with very similar results to those obtained after its oral administration, but obtained with a total average dosage of 81 grammes in place of an average of over 3 000 grammes by oral use, a very material saving in cost per case. A discussion of the whole series with a comparison with hydnocarpus oil treatment brings out the following points, including the effects of injections of the much less expensive sulphone, diamino-diphenylsulphone, in eleven cases. Good photographs of six cases before and after treatment are given, but unfortunately the table relating to them does not give the number of pages referred in the text in the case of two, and in two others such data do not appear to correspond with those in the text. The first part of the paper concludes that for oral use sulphetrone is superior to diasone, a conclusion others had previously reached. About 30 per cent of those treated with diasone showed reactions, but they later subsided in spite of the drug being continued without rest and they did not recur in any cases after 1000 tablets had been given. Furthermore, under this drug the only cases that became negative were in boys who received relatively large doses, so maximum dosage is indicated, but the high cost rarely allowed more than 4 tablets a day to be given. With oral sulphetrone only one patient had a very severe reaction and foot drop followed. Four of the nine became negative within two years.

Owing to the high cost of diasone and sulphetrone given orally, which prohibits its use on a large scale, and the necessity of giving daily intravenous doses of promin, the author has tried injection of sulphetrone with interesting results. The active principle of all three, namely, sulphone or diamino-diphenylsulphone has also been tested by injection, but the case notes and comments show that the latter gave rise to more severe reactions. Treatment by sulphones in general is also compared with that by the injection of hydnocarpus oil. The best results were obtained by subcutaneous injections of 7 cc

of 50 per cent. sulphethione in water twice a week. On the other hand sulphone in doses of 1 to 1.5 gramme a week in a strength of 25 per cent. suspension in groundnut oil is probably the most potent remedy but one which produces severe reactions in the form of anaemia, giddiness and sickness and peripheral neuritis sometimes of an alarming degree. This prohibits its use on a large scale until a safe dosage is found. In early lepromatous cases hydnocarpus treatment is the best. This paper should be studied by all interested in leprosy treatment.

L. Rogers

FLOCH H. & CAMAIX R. Sur le traitement de la lèpre par les sulfones en Guyane française. (Treatment of Leprosy by Sulphones in French Guiana.) Institut Pasteur de la Guyane et du Territoire de l'Est. Publication No 179 1948 Sept. 11 pp. [14 refs.]

As in French Guiana lepromatous cases constitute only one-third of the total cases the sulphone treatment had been used in all three types with interesting results. Both promin and diasone have been used in doses advised by early American workers in patients under the age of 20 years as a rule. Details are given of some of the cases and the following are the main conclusions arrived at after treatment for eight to eighteen months. In lepromatous cases retrogression was noted as described by earlier workers. In nine "indifferent" forms improvement was noted in six, aggravation in two and no change in one so the results were less clear than in the lepromatous type. Some degree of improvement in nerve symptoms was also noted. In three tuberculoid cases after 20 months two were stationary and one was aggravated. The histological and bacteriological changes were as described in the above paper by the same authors. Any signs of anaemia were easily controlled by iron. In only three lepromatous cases were reactions seen. The authors consider that the action of sulphones is to destroy the lepra bacilli in the more vascular lesions as well as those which enter the blood stream.

L. Rogers

FLOCH H. & CAMAIX R. Sur le traitement de la lèpre en Guyane française par les dérivés sulfonés. (Sulphone Treatment of Leprosy in French Guiana.) Bull Soc Path. E et 1948 v 41 Nov. 11/12, 646-9

The authors report on trials of promin and diasone during sixteen months. They were used in doses and with intervals similar to those in the case of the original trials at Carville and moderate degrees of anaemia met with were readily controlled by iron. Only a few slight reactions were met and they subsided readily. Diasone was not well borne by some patients. Promin was used in three tuberculoid and thirteen indifferent undifferentiated cases in children with no clinical improvement except in two pre-lepromatous indifferent cases in which histological examinations showed some trophic reaction as well as with round cell infiltration and return to the indifferent type but little change was found in frankly indifferent cases. In the case of nine lepromatous cases there was a definite slow retrogression of the clinical symptoms in the following order. First nasal and conjunctival signs disappeared next trophic ulcers healed, followed by decrease of lepromatous and dermal infiltrations which was slowest in the case of the ears and lastly improvement in sensation occurred. Further the mental outlook of the patient and their general condition much improved. Microscopically the lepromatous structure was gradually replaced by connective tissues and in one case there was a return to the indifferent type. The lepra bacilli became much reduced, granular forms became dominant

JAFFÉ R. Parasitosis intestinal como causa de muerte en Venezuela. [Intestinal Parasites as a Cause of Death in Venezuela.] *Rev. Sanidad y Asistencia Social* Caracas, 1945 Apr v 10 No 2, 283-92, [17 refs.]

The author has conscientiously tried to separate patients dying with and those dying from helminthic infestation. Many persons harbour *Ascaris* for example in large numbers without serious harm, whereas others with fewer may owing to migration of the worms or to their position, die from, say, liver abscess or suppurative cholecystitis. Again, *Necator* is common but among 3700 autopsies the author found 14 in which he is convinced death was due to this infestation: the worms were present in enormous numbers and there was fatty degeneration of the heart and intense anaemia. He does not exclude those who died as a result of taking carbon tetrachloride regarding such a fatality as due though indirectly to the infestation. The cause and effect sequence is less clear in some of the cases recorded: for example a child of 7 years with innumerable *Trichuris* in the large intestine and a fatty liver for the child had also tuberculosis of the hilar glands and of the spleen and schistosomes in the portal vein. Another had *Ascaris* and schistosomes also. *Enterobius vermicularis* if in large numbers may cause death, says the author but only indirectly through cachexia and secondary infection.

H. Harold Scott

BARLOW C. H. Une théorie sur la ponte de *Bilharzia haematobia*. [A Theory concerning Egg Deposition by *Schistosoma haematobium*.] *A. n. Parasit. Humaine et Comparée* 1949, v 23 Nov, 58 301-4

This theory is concerned with the method of egg deposition in the bladder wall by *Schistosoma haematobium* and the escape of the eggs to the lumen of the bladder. It is suggested that the female worm penetrates the capillary in which she is lying and lays her eggs in a small pocket or cyst in the bladder wall close to its inner surface. Having filled the cyst with eggs she returns to the capillary leaving a canal between capillary and cyst through which she returns again to refill the cyst with eggs when it has emptied itself. The eggs escape during micturition which causes the rupture of a weak point in the bladder wall near the cyst.

The theory is supported on various grounds. It is argued that if the eggs make their way slowly and fortuitously through the tissues from various levels, according to the procedure generally accepted at present they would be at different stages of development on arrival in the bladder lumen but this is not the case. The constant numbers of eggs which daily appear in the urine is also held to conform more with the new theory than with the old.

Clinical data in support of the theory are adduced from the results of examining urine collected during a single micturition in a series of centrifuge tubes of 50 ccm. capacity. It was noted that (1) the first part of the urine was clear with only a little fresh blood; (2) the next portion contained blood and a number of conical plugs of clotted blood which enclosed a few eggs mostly with inactive miracidia. Their appearance corresponded with the rupture of the cysts before the eggs are discharged; (3) the next portion contained much blood and some eggs. Evidently after the blood clots are expelled profuse bleeding occurs; (4) the last portion was inundated with eggs forced out of the cysts by muscular contraction of the bladder wall. The same sequence of events was observed with several repetitions of this procedure and also with the author's own bilharzial infection.

Evidence that the adult worms are situated very close to the spot where the eggs are evacuated from the tissues, was obtained from the author's own infection, in which a number of papules on the anal skin were found to be full

showed that all patients but one in each scale of dosage were passing viable ova, though there is an "impression" that the number was less than initially.

JANSEN P. La bilharziose intestinale dans la région de Tora (province orientale du Congo belge) [Intestinal Schistosomiasis in Tora, Belgian Congo.] *Ann Soc Belge de Méd Trop* 1948 Dec. 31 v 28 N 4 193-410 1 pl.

During a stay of two-and-a-half years in Tora which is situated on the border of Haut Ituri in the Eastern province of the Belgian Congo studies were undertaken of the schistosomiasis prevalent in the region. The area is a gold-mining one with over two thousand Africans employed in the industry. Much water is needed, and this is stored in large shallow barrages rich in vegetation, interconnected by canals. The conditions are therefore peculiarly suitable for snail propagation and *Planorbis* is very plentiful. Microscopical examination usually of single specimens of stool, showed 287 / 411 otherwise apparently healthy Africans to be passing *Schistosoma mansoni* eggs. 358 of these were adults of whom 86 per cent. were found infected and 51 were children, 73 per cent. of these being found to be infected. None of these Africans suffered from alimentary disorders. On sigmoidoscopy of 50 persons, 23 of them known to harbour parasites, no abnormality was observed.

On physical examination two-thirds of those known to harbour the parasite had an enlargement of the liver. Tests of liver function did not prove helpful in diagnosis and estimations of blood protein yielded inconclusive information. Biopsy showed schistosome ova in the liver to be surrounded by mononuclear cells and fibroblastic inflammatory reaction. The lesions appeared largely to be limited to a granulo-fatty degeneration immediately around the ova and well-defined liver cirrhosis was but rarely seen.

VAN DER KUIP E. Planorbidae Records of the Netherlands Antilles. *Ann J Trop Med* 1949 Mar v 29 No. 2, 254-61 18 refs.]

Tropicorbis *sauvignoni* Pilsbry is found on the islands of Curaçao and Bonaire. Other *Tropicorbis* species may also be present. *Australorbis plat anus inguavis* Wagner and *Helisoma d. r. melleolens* Pilsbry were imported into Curaçao from Venezuela. The *Australorbis* species was found only once in Aruba in an aquarium. Autochthonous cases of schistosomiasis have never been reported from the Netherlands Antilles.

SCHREIBER Freda G & SCHUBERT M. Experimental Infection of the Snail *Australorbis plat anus* with the Trematode *Schistosoma mansoni* and the Production of Cercariae. *J Parasitology* 1949 Feb. v 35 No. 1 91-100 1 fig (10 refs.)

The work described here was undertaken to obtain data of value to laboratory workers concerned with the chemotherapy of schistosomiasis in experimental animals and was designed to find out (1) the percentage of snail that becomes infected on exposure to miracidia under a uniform set of conditions (2) the time at which half the miracidia die under these conditions (3) the production of cercariae by infected snails under specific controlled conditions (4) the time at which half the infected snails die (5) the time at which half the cercariae die under a few specific conditions.

(1) Eggs of *S. mansoni* were obtained from faecal pellets passed by experimentally infected mice or hamsters and hatched after standing 1 to 7 hours in

water at 28°–30°C Snails were exposed individually to one or to 5–7 miracidia and examined for emission of cercariae 4 to 10 weeks after exposure Of 127 snails exposed to one miracidium each, 8 per cent became infected Of 1,698 snails exposed to 5–7 miracidia each, 50 to 60 per cent became infected

(2) Miracidia were placed in a number of beakers at 24° to 26°C and counted at intervals of 2 hours After about 8 hours half the original number were dead

(3) Counts of emerging cercariae were carried out for periods of 2 months on batches of infected snails, generally about 4 or 5 times each week The weighted average number of cercariae liberated per snail per day was 698, the range being 14 to 4,158 The liberation on Mondays (i.e., after 2 days' rest from stimulation) was usually higher than on other days Stimulation was by warming at 30°C or by warming plus illumination The combined stimulant increased the average emergence by 30 to 90 per cent of the emergence produced by warming alone

(4) The time after the first liberation of cercariae at which half the snails died was 4 weeks

(5) All cercariae incubated at 30°C were dead 20 hours after emergence and half were dead between 8 and 16 hours

LUTTERMOSER, G W & CASTELLANOS, J V Observaciones sobre la propagación y la destrucción del caracol, *Australorbis glabratus* Say, 1818, vector de *Schistosoma mansoni* (bilharzia) en el Valle, D F [On the Multiplication and Destruction of *Australorbis glabratus*, the Vector of *Schistosoma mansoni* along the El Valle River, Federal District, Venezuela.] *Rev Sanidad y Asistencia Social* Caracas, 1945, Feb, v 10, No 1, 109–48, 4 maps & 6 figs (5 on 1 pl) [25 refs] English summary

This question is of much local importance because the rate of infestation among the people is high, the vector abounds and there is a heavy contamination of the water-courses and their banks with excreta and many persons use this water A careful study extending over 3 years was undertaken to determine the prevalence of *Australorbis glabratus* in the Federal District of the State of Miranda in Venezuela Line maps show very clearly that for long distances of the main rivers this snail is not found, but in the lower reaches of the Valle River from Turmero to its junction with the Rio Guaire they abound, i.e., in the northern hilly districts of Venezuela, and here *Schistosoma mansoni* is endemic. The river bed here is less steep and the flow is less rapid, there is abundant algal and other vegetal growth the sewage of the population drains into it and the water contains much bicarbonate of calcium, all conditions favourable to the propagation of the snail In the dry season they breed copiously and in the wet season they are washed downstream to other parts

In dealing with this problem it was found that attempts to eliminate the vector from certain areas were, however successful temporarily, ineffectual in the long run because water coming down from the upper reaches resulted in re-infestation Two things were necessary to prevent the passage of infected sewage into the river and to start dealing with scourge at the head-waters first and then progress gradually downstream The intake site for irrigation must be carefully selected to prevent passage of the snails into the irrigation canals and these canals should be lined and kept clean Sand-filtration is not enough to remove infection from highly infested water for guinea-pigs were infested by water filtered through a depth of 100 cm of sand Photographs are

reproduced showing the state of the terrain which allows and fosters the propagation of *Austrocypris glabratus*

LUTTENMOSER G. W. Estudios sobre el caracol vector del *Schistosoma mansoni* en la ciudad de Maracay y Alrededores (Estado Aragua) con recomendaciones para luchar contra el. (The Vector of *Schistosoma mansoni* in Maracay and Its Environs and Recommendations for dealing with it.) *Rev. Sanidad y Asistencia Social* Caracas 1945 Feb., v. 10 No. 1 149-63 17 figs. on 3 pls. & 1 map. English summary.

Maracay is the capital of the State of Aragua and lies north-east of the Valencia Lake. Nearly 100 places were selected for examination for *Austrocypris glabratus* the intermediate host of *S. mansoni*—rivers, drains, irrigation canals, reservoirs etc. and at 7 of them the snails were found, most in the unlined irrigation canals. In 16 of 31 unlined but in 3 only of lined canals. In these three there was much vegetation, so that the water-flow was obstructed. Where the flow was good and the canal kept clean the snails found no chance to develop. Only 1 175 specimens of the mollusc were collected altogether—a very small number—and in 3 only of the 7 samples were they found to be infested with cercariae of *S. mansoni*. These cercariae remain infective for some time because persons living 2½ kilometres below the place where the snails existed were infected. One place heavily infested was a tank supplied with well water—the snails probably gained entrance to the tank by plants carried there or by birds or in the material used for its construction. From the tank the canals became infested and, to eradicate the vector, it will be necessary to empty out all or nearly all the water, paint the whole of the inside with strong milk of lime and wash it well with a strong jet of water. A series of photographs shows some of the poorer dwellings, the district canals lined and unlined.

JAFFE R. MAYER M. & PERAZO C. F. Estudios biológicos y anatomopatológicos en animales infectados con un solo sexo de *Schistosoma mansoni* (Biological and Pathological Studies in Animals Infected with Male *Schistosoma mansoni*). *Rev. Sanidad y Asistencia Social* Caracas, 1945 Feb., 10, No. 1 85-107. English summary.

Fant in 1927 stated that in snails collected in China in the dry season he found only male worms and he concluded that female worms were less resistant to inimical circumstances. In Caracas where a certain degree of moisture is maintained in the dry season by irrigation, no such preponderance of sex was observed. According to Gorges, Egyptian splenomegaly results from infestation by male worms. This the present authors could not confirm. Using guinea-pigs, rat and rabbits, they found a large spleen in a rat infested with female worms only and in a guinea-pig with male infestation only—yet again other animals heavily infested with both male and female might have normal spleens.

The pathological lesions of necrosis and pigmentation in the liver, the spleen, intramuscular infiltrations, endarteritis, peri-arteritis and phlebitis were the same in those infested with male worms only and in those infested with worms of both sexes. In fact of 30 animals infested by worms of one sex only (males) 8 showed necrosis of the liver whereas 9 out of 78 of those infested with both males and females showed this lesion. If one can draw any inference from so small a number it would seem that male worms are more likely to cause the necrosis, at all events the lesion cannot be ascribed to the presence of ova but is due to toxins secreted by worms of either sex.

MAYER, M, LUTTERMOSER, G W & PIFANO C, F Investigaciones diagnosticas sobre la Schistosomiasis Mansoní en la ciudad de Maracay y Alrededores inmediatos (Estado Aragua) [Study of Infestation by *Schistosoma mansoní* in Maracay and its Immediate Neighbourhood] *Rev Sanidad y Asistencia Social* Caracas 1945, Feb, v 10, No 1, 165-74, 1 fig English summary

The following means of diagnosis of schistosomiasis in the Maracay district of the State of Aragua were used (1) History, including age, place of residence, contact with infested water (river, irrigation canals, wells), (2) Clinical examination and measurement of liver and spleen, (3) Examination of faeces, (4) Intradermo-reaction and, if this was negative, Fairley's complement fixation test

The numbers examined were small but the findings are, nevertheless, of interest Only 127 were examined, 76 of them school-children The intradermal reaction was carried out in all and in the cases of 7 suspected persons, who gave a negative to this reaction and faecal examination, the complement fixation test was made Of the 76 children, 42 were from 6 to 10 years of age and 3 of these had ova of *S. mansoní* in their stools, of 34 between 11 and 15 years 15 were positive Of 60 persons living in the suburbs of the town who were examined, 17 were below 15 years of age and 11 of them were passing the ova, 43 were over 15 years and 26 of them were passing ova, *i.e.*, 37 out of 60 Twenty-six had enlarged spleens, but, though malaria is present, it is believed that this symptom is more often due to the helminthic infestation In 4 only were malaria parasites seen (*P. vivax*) in whom the intradermo-reaction was negative This reaction was positive in 13 out of 40 school-children between 6 and 10 years of age and in 15 out of 30 between 11 and 15 years Fifty-five of the general (not school) population were tested by the skin reaction and of 7 below 5 years of age 3 were positive, 5 out of 8 between 6 and 10 years, 1 out of 5 between 10 and 15 years, and 26 out of 35 above that age

MAYER, M & PIFANO C, F El diagnostico de la schistosomiasis por intradermorreacciones con un antígeno preparado de vermes adultos de *Schistosoma mansoní* (Estudio fundamentado en 5000 intradermorreacciones) [Diagnosis of Schistosomiasis by Intradermal Reactions] *Rev Sanidad y Asistencia Social* Caracas 1945, Feb, v 10, No 1, 3-44, 5 figs [25 refs] English summary (10 lines)

This is a careful study and carried out with much attention to detail In an introductory historical account of the intradermal reaction in *S. mansoní* infestations the authors give due credit to Hamilton FAIRLEY as the pioneer in this work They describe in detail the method of preparing their own antigen which they call *Bilharzine* Early attempts were made with cercariae, collecting them in large numbers, centrifuging, sedimenting and filtering, but this was hazardous through handling the cercariae, they, therefore, devised a plan for using adult worms They prepare their antigen as follows At first naturally infested snails were used as they are abundant in Distrito Federal, but later they bred them from snails infested by human faeces or the livers of experimental animals The cercariae were allowed to penetrate guinea-pigs and rats whose abdomens had been shaved The latter seemed to be the more resistant to infection and guinea-pigs are to be preferred Forty days later adult worms were present in the liver and a little later still in the small vessels of the mesentery and walls of the intestine The animals were killed and the worms obtained by macerating the liver and the mesentery in saline A good yield would be 100 worms from a rat and 300 or more from a guinea-pig The

worms were dried, pulverized and suspended in phenolized saline. Later Coca fluid was used. This contains sodium chloride 0.5, sodium carbonate 0.05 (sodium bicarbonate 0.28 per cent according to Stitt) and phenol 0.4 per cent. subsequently merthiolate 1:5000 replaced the phenol. The strength of the suspension was about 500 worms in 3-4 cc. of fluid. It was placed in the ice-box for 5-8 days with frequent shaking and then centrifuged and filtered, first through paper and then through a Seitz filter. The product will keep for several months.

The reaction is graded thus: 0 where there forms a papule not more than 1 cm. in diameter with defined edges; \pm papule of diameter 1 cm., with irregular edge; + papule 1-1.5 cm., edges irregular; ++ 1.5-2 cm. papule edges irregular or with pseudopods; +++ 2.5-3 cm., similar in appearance. These are illustrated by diagrams and photographs.

Results—Positive in 163 out of 171 patients, 95.3 per cent. Of 253 controls not one was positive. Helminthiasis being common in Venezuela, the test was carried out on patients with cestodes and nematodes, but the results were negative. On infestation with other trematodes such as *Fasciola hepatica* a report will be issued later.

The test was made on 4045 unselected persons and 1,900 (46.9 per cent) were positive. 179 others (3-4) were doubtful. The positive figure is also the average of inhabitants of Caracas and its environs who harbor *S. mansoni*. A positive reaction may appear at any time from 18 to 35 days after infestation. Since the reaction persists for some long time even more than a year it is merely a proof of present or past infestation. Most of those reacting were between 20 and 40 years old.

Other tests were made with antigens similarly prepared but with male and female worms separately. According to a protocol in the paper 37 persons were tested with all three antigens male female and both. The results of the two former were not very discordant but the "male" antigen was little better than the "female" the bisexual was much the best of all. Another antigen used was one prepared from a liver with abundant eggs of *S. mansoni* part was treated with ether part was not. The ether treated antigen was rather the better but the Bulharszue of the authors proved by far the best of all. Another was made from an infected spleen but it was not of much value.

MAYER M. & PIFANO C. F. La reacción de desviación del complemento según Fairley en la Schistosomiasis Mansonii. Estudio fundamental de 1832 reacciones. (Complement Deviation in Schistosomiasis mansonii. Rev. Sociedad's Asistencia Social, Caracas, 1935 Feb., v. 10 N. 1, 85-95 [25 refs. English summary].

This is a study of Fairley's complement fixation reaction and the authors' confirmation of its use and of methods derived from it. Comparing his (the authors') antigen from *S. p. male* with that prepared from the hepato-pancreas of *Australorbis glabellus* infested with cercariae of *S. p. male* with other means and also of uninfested snails. Those interested should consult the original for the paper is too full and congested for abstract and comprises a dozen printed pages. The result may be epitomized by saying that among 281 persons proved to be infested by demonstration of ova in the faeces 217 (81 per cent) were positive whereas among 120 from non bilharzial district and 51 suffering from other diseases such as malaria, ankylostomiasis, amebiasis, cancer of the liver, cutaneous leishmaniasis et non va positi. After course 1 tartar emetic 5 per cent of the positive reactors became negative. After second course 12 per cent were negative. The authors conclude: A positive test

does not signify that living worms are present at the time of examination. It is for the physician to decide whether or not the clinical symptoms presented demand treatment."

OTTOLINA, C & ATENCIO M, H Nuevos caminos para el diagnostico clinico preciso de la Schistosomiasis Mansonii [New Methods for the Accurate Diagnosis of Schistosomiasis mansonii] *Rev. Sanidad y Asistencia Social* Caracas, 1945 Feb, v 10, No 1, 185-215, 2 figs [Bibliography]

The new methods described and evaluated are two liver and rectal biopsy. Faecal examination for ova often fails and ova have been found for the first time after as many as 20 examinations. The complement fixation method of Farley is not specific in that it is given also by the Fasciolidae. Yet again, as is well known, infestation may persist after apparent clinical cure.

Liver puncture is described in minute detail, for which those interested should consult the original, if they are not already *au fait* with the procedure. The material obtained is digested in 4 per cent potash, after which the ova are easily found. It is known, however, that the female worms oviposit preferably in the inferior mesenteric veins and the eggs are found in the rectal walls, and the recto-sigmoidal region or the upper part of the rectal ampulla is usually particularly rich in ova. Again, the procedure for obtaining biopsy specimens from this site are detailed and illustrated. The ova may be seen in these specimens even when the liver biopsy proves negative, but in none of the authors' cases did the reverse obtain, the rectal biopsy was always positive if the liver had shown ova.

A table gives details of 12 patients, 8 had had no treatment and all were positive, one had received two courses and, with brief negative intervals, was again shown to be positive by rectal biopsy. Three had been treated and were regarded as clinically cured, nevertheless in only one was the cure confirmed by rectal biopsy, both the others showed ova to be present, in one there were 27, in the other 38 in a single preparation.

DA SILVA, L C T Splenectomy in Schistosomiasis mansonii *Puerto Rico J. Pub Health & Trop Med* 1948, Sept v 24, No 1, 69-89, 7 figs [Refs in footnotes] [Spanish version 90-103]

In the agricultural regions of Pernambuco, Brazil, it is estimated that from 36 to 50 per cent of the population suffer from infestation by *Schistosoma mansonii*. The number of patients with parasitic splenomegaly seen in the hospitals is increasing, though the diagnosis is not easily established, owing to the infrequency with which the schistosomes or their eggs are found in the parenchyma of the spleen. Sixty patients with splenomegaly were operated upon by the author during 6½ years. Examination of the faeces for schistosome ova was positive in 54 and in the remaining 6 the diagnosis was established by liver biopsy in 4 and by subsequent post-mortem examination in 2. The ages of the patients ranged from 10 to 44 years, with maximum incidence at ages 15-24. Ascites was present in 15 patients. The most frequent symptoms were diarrhoea in 74 per cent, general weakness in 76 per cent, fever in 67 per cent and epistaxis in 64.7 per cent. Haematemesis, due to rupture of oesophageal varices, occurred in 56.6 per cent. The Wassermann reaction was tested in 31 patients and proved to be positive in 14, this test may be strongly positive in *Schistosoma mansonii* infestations, even in the absence of syphilis [but no evidence is given to support this statement]. Splenectomy is indicated for the relief of portal tension and abdominal distension and for correcting leucopenia, repeated attacks of haematemesis constitute an urgent indication for operation.

Treatment of anaemia and helminth infestations precedes operation, but the author does not give a pre-operative course of antimony as he considers that in heavy infections it undermines the patient's resistance which needs to be high to withstand the operation. A course is however given after operation.

High spinal anaesthesia was used except in emergency operations for which general anaesthesia was preferred. A left mid-rectus incision with careful separation of all adhesions before ligation of the pedicle was the usual method of approach but for very large spleens a thoraco-abdominal incision was found to give better access. Post-operative haemorrhage from small vessels at the back of the stomach and spleen is a very real danger to be guarded against by careful haemostasis. Blood transfusion was only exceptionally given. There were 15 post-operative deaths in the series of 60 cases from internal haemorrhage haematemesis from oesophageal varices or from pulmonary complication. The best results were in young patients without cirrhosis or ascites and with over 3 million erythrocytes per cmm. and Hb. of 60 per cent. or more.

In a table a summary of the blood changes in 9 patients at intervals of one to 24 months after operation is given and compared with the condition on admission. All show improvement in both red and white cell counts.

CRANCE, M. R. A. & MANSOUR, T. L. A Kymograph Study of the Action of Drugs on the Liver Fluke (*Fasciola hepatica*). *Brit. J. Pharmacol. & Chemotherapy*, 1949 Mar. v 4 No. 1 7-13 4 figs. 10 refs.

"1. It is possible to obtain rhythmical kymographic records from fresh bovine flukes suspended in Ringer's solution at a pH range from 6.5-8.5. These movements are maintained for a period of 1 to 24 hours and frequently as long as 6 hours.

"2. The effect of known anthelmintics and of a number of other drugs, particularly those affecting the neuromuscular mechanism of vertebrates, has been tested on this preparation by allowing them to act for a maximum period of 45 min.

"3. At the end of this period the addition of amphetamine restores rhythmical activity provided the drug has had only a paralytic action on the fluke. In this way it has been possible to distinguish between stimulant, paralytic and lethal drugs.

"4. It is suggested that the possible reason why the chlorinated hydrocarbons are so effective as anthelmintics against *F. hepatica* is that they combine the stimulant action at low with the lethal at higher concentrations. A number of other anthelmintics have been shown to have other types of combined action.

"5. Comparison with the similar test in *Acanthamoeba* (Baker 1945) reveals that the liver fluke, as a representative of the platyhelminthes is sensitive to all the drugs which affect *Acanthamoeba* and in addition to umbelliferone, pelletterine extract, flurazepam, and certain others. The umbelliferone of this comparison is discussed.

HARANT, H., LAPEYSSONNIE, L. & LANCIEN Sparganose kystique chez un noir du Gabon [Cystic Sparganosis in an African from Gabon] *Bull Soc Path Exot* 1948, v 41, Nos 11/12, 666-7

An African patient from Gabon, French Equatorial Africa, was admitted to hospital in June, 1948, with a cystic tumour in the right lumbar region accompanied by pain on moving or bending the trunk, which had begun in 1943. The tumour, situated latero-vertebrally, was hard, about the size of a nut, and painful on pressure. Fluid could not be aspirated from it. There was an eosinophilia of 24 per cent, the Casati test was negative, faecal examination showed *Strongyloides*. The cyst was removed from the subcutaneous tissue under a local anaesthetic and on being opened revealed a flat worm 4 cm long which moved like a *Taenia proglottis*.

The authors comment on the geographical distribution and host localization of sparganosis generally and the difficulties connected with the accurate identification of plerocercoids, of which the present instance is an example

J J C Buckley

DOLD, H. & THEMME, H. Ueber die Möglichkeit der Uebertragung der Ascaridiasis durch Papiergeld [The Possibility of Transmission of *Ascaris* by Paper Money] *Deut med Woch* 1949, Apr 1, v 74, No 13, 409

The authors state the common methods of acquiring *Ascaris* infestation by eating raw or inadequately cooked fruits and vegetables which have been fertilized by human excreta. They then recall the work of DOLD and CHEN YU HSIANG of 30 years ago when they showed that typhoid, paratyphoid, dysentery, cholera and diphtheria organisms might cling to paper money and remain viable for a time. They wondered whether the ova of *Ascaris* might not similarly remain viable and be transmitted. They, therefore, tested whether ripe *Ascaris* ova on the fingers could be transferred to notes and *vice versa*, and next determined that these ova would live in an atmosphere of 50 per cent moisture at 18°C for some 5 weeks. Now, the average humidity in Germany in the middle of the year is 70-80 per cent [say the authors] and the temperature for development of the ova is 15°C. Paper money is usually carried in a trouser pocket or a coat pocket where the temperature is above 15°C. They took 20 old Reichsmark notes, much used and "correspondingly dirty", washed them in 40 cc of filtered and sterile physiological saline and the fluid was then centrifuged at a low speed for 5 minutes, in the deposit were found fertilized *Ascaris* ova.

H Harold Scott

DA SILVA, L. S. Ascariasis and its Dangers *Med J Malaya* 1948, Sept, v 3 No 1, 41-8

In the General Hospital, Singapore, approximately 25 per cent of the children admitted are infected with *Ascaris lumbricoides*. During three years (1939-41) the author performed 1,350 autopsies on children and he claims that no less than 73 of these children died of ascariasis.

This paper consists mainly of a tabulated record of these 73 cases. They include 14 cases of acute abdominal complications, there were seven cases of hepatic abscess, with lung abscesses in three of them, suppurative cholangitis with peritonitis in five cases, intestinal obstruction by a ball of roundworms, a perforated ulcer of the ileum, each in one case, there was also a case of otitis media with a worm in the Eustachian tube. Roundworms were present in the abscesses in all these cases.

The clinical picture of the less dramatic cases was that of secondary anaemia, followed by enteritis and often terminal pneumonia.

WILLIAMS W. J. SCHELLING V. & HARTMAN F. W. Action of some Alkylhydroxybenzenes on Pig Ascaris *in vitro*. *Amer J Trop Med* 1949 Mar. v 29 No. 2, 241-5 2 figs.

"Several new substituted alkylhydroxybenzenes have been tested for their ascaricidal properties both by the variable exposure method and the kymograph method.

"One of these 2-ethyl-4-chloro-6-hexylresorcinol seems to be more active than hexylresorcinol *in vitro*."

MALDONADO J. F. HERNÁNDEZ MORALES F. FOX I. & THILLET C. J. The Incidence of Filariasis bancrofti in Government Institutions for Children in Puerto Rico. *Puerto Rico J Pub Health & Trop Med* 1948 Dec. v 4 No. 2, 121-34 Spanish version 135-49]

A survey of the incidence of filariasis in three institutions for children in Porto Rico revealed by microfilarial examination percentage infection rates of 3.8 1.3 and 10.4 respectively. In the last group clinical evidence of the infection was slight. Examination of 693 mosquitoes collected in the building housing this group showed 14.7 per cent. of them to be infected. (Detail of these are tabulated.)

Of the mosquitoes collected from the three institutions 83 per cent. were *Culex quinquefasciatus* (C. *fat* genus) *Aedes sollicitans* and *Aedes aegypti* were infrequent and were never found to be infected. The mosquito survey indicated that although transmission of the parasite to the vector was occurring intensively, transmission from vector to human beings was more difficult.

J. J. C. Duckler

KERSHAW W. E. with a statistical analysis by R. L. FLACKETT. Observations on *Lilomacoides curvis* (Travassos, 1919) Chandler 1931. I. The Development of the First Stage Larva. *Ann. Trop. Med. & Parasit.* 1948 Dec. v 42 No. 4 37-99 7 figs. on pl. & 5 text figs. 26 refs.

From the aspect of experimental chemotherapy against filariasis in cotton rats, a complete knowledge of the normal behaviour and appearance of the microfilaria in all phases of its existence is very desirable. The present study was designed to fill a gap in the knowledge of the ethology, development and morphology of the larva of *L. curvis* from the time of birth to the appearance in the peripheral blood. Measurement and observations were made on the larvae in three different stages: those just emerged from the maternal host, those from the pleural spaces of the host and those from the peripheral blood.

The mean lengths of larvae numbering 200, 220 and 60 respectively from three female worms, were respectively 88.8µ, 88.76µ and 84.5µ. The mean length of 500 larvae from the pleura was 71.68µ and that of 500 larvae from peripheral blood was 77.93µ. There is thus an increase in length during the period of migration from the parent worm to the blood during which there is also an increase in nuclear complexity. Of special interest however is the shedding of a sheath—the stretched out vitelline membrane—immediately after the subsequent development of a true larval sheath during its migration in the peripheral blood. This is discarded in the gut of the insect vector when the larvae are ingested.

{In the light of these observations it should be necessary now to re-examine the nature and origin of the sheath in such forms as *W. bancrofti* which has been considered by early investigators and is therefore accepted by many not to be a true larval sheath, but to rely on an enclosing membrane derived from the egg shell or vitelline membrane.

J. J. C. Duckler

BUEDING, E **Studies on the Metabolism of the Filarial Worm, *Litomosoides carini*** *J Exper Med* 1949, Jan 1, v 89, No 1, 107-30, 2 figs [46 refs]

This investigation on the filarial worm *L. carini*, a natural parasite of the cotton rat, was undertaken to gain a better understanding of the mode of action of filaricides and hereby to aid in the selection of new therapeutic agents. For metabolic studies the worms were obtained from the pleural cavity of naturally infected cotton rats and were washed and maintained in a medium containing Na, K, Ca and Mg chlorides, to which was added a sodium phosphat buffer of pH 7.6. The metabolism and motility of the filariae were influenced by the nature and concentration of the metallic ions present in the medium as well as by its pH value. For respiration experiments, 15 to 25 mgm of worms in 0.8 ml of the above medium were used in a conventional Warburg apparatus at 37.5°C, with cups of 4 to 5 ml volume. The acids produced were determined before and after incubation as were also total carbohydrate and glycogen. It was found that the rate of oxygen uptake of the worms was increased in presence of glucose and remained constant over a period of at least 7 hours, during which time motility was preserved. Fructose and mannose acted like glucose whereas other common substrates including lactate and pyruvate did not. After a period of anaerobiosis, during which glucose was used up, oxygen uptake was not increased and in this respect *L. carini* differs from other helminths. Aerobically the glucose was converted to lactic and acetic acid and glycogen was synthesized. A polysaccharide other than glycogen was also present in the worms. During anaerobic incubation in presence of glucose, the polysaccharide content of the worms decreased and lactic acid was predominantly formed along with a small amount of acetic acid. Aerobically, lactate and pyruvate were utilized to a smaller extent than glucose. Respiration and metabolism were influenced to a considerable extent by fluoroacetate, iodoacetate, p-chloromercuric benzoate, cyanide and certain cyanine dyes. The latter group of substances have been shown by WELCH *et al* [this *Bulletin*, 1947, v 44, 1015] and by PETERS *et al* [below], to be effective chemotherapeutic agents in cotton rat infections with this parasite. The present author found that two substances (Chemotherapy-Centre Nos 348 and 863) were effective inhibitors at low concentrations and decreased the oxidative metabolism which is apparently essential for the survival of *L. carini*. Similar changes were noted in worms from cotton rats themselves treated with these substances. The chemotherapeutic action of the cyanine dyes in filariasis of cotton rats appears to depend upon their inhibitory effect on the respiratory metabolism of filariae. *J D Fulton*

PETERS, L, BUEDING E, VALK, A D, Jr, HIGASHI, A & WELCH, A D
The Antifilarial Action of Cyanine Dyes. I. The Relative Antifilarial Activity of a Series of Cyanine Dyes against *Litomosoides carini*, in Vitro and in the Cotton Rat *J Pharm & Exper Therap* 1949, Feb, v 95, No 2, 212-39 [16 refs]

The *in vitro* and *in vivo* action of certain cyanine dyes against the filarial worm *Litomosoides carini* of the cotton rat has been reported by WELCH *et al* [this *Bulletin*, 1947, v 44, 1015], and by BUEDING and also PETERS (*Ann New York Acad Sci* 1948, v 50, 115, 117). The activity appeared to be specific for that filarial species. CULBERTSON *et al* [this *Bulletin*, 1944, v 41, 772, 1945, v 42, 136] and other authors have used antimony compounds to treat this infection with some degree of success. In the present investigation a search has been made for filaricides, of non-metallic type, with activity against adult worms. Cotton rats naturally infected with *L. carini* used in screening

tests were treated intraperitoneally with an amount of drug approaching the maximum tolerated every 8 hours up to a total of 18 doses, in order to detect activity. The animals were killed 40 hours or longer after the last dose and adult worms, when present in the pleural cavity were removed to nutrient medium and observed at the same time as those from untreated cotton rats. THRENEW & BERTMAN (this Bulletin 1949 v 48 pp) have pointed out that results, obtained with wild cotton rats infected for an unknown period of time must be interpreted with care. The first compound to show marked activity was a member of the group of cyanine dyes—(1-aryl-2, 5-dimethyl-3-pyrrole) (1-6-dimethyl-7-quinoxaline)

dimethincyanin chloride which as a class possess tertiary and quaternary nitrogen atoms separated by a conjugated chain of C atoms (*i.e.* with alternating single and double bonds). This substance allotted the number 348, was very active and killed all adult worms either after repeated well tolerated doses or after a single dose near the maximum tolerated. With the antimony compounds Neostibosan and Anthiomaline on the other hand a cure could not be obtained. This substance 348 reduced the motility of adult *L. carinii* at a dilution of 1/1 million and affected their oxidative metabolism at a dilution of 1/40 million. Decrease in the respiration of mammalian tissues was affected only by a concentration 1,000 to 1,000 times as great. Cyanine dyes in general appeared to exert their effect through action on oxidative enzymes. All the drugs which were active *in vivo* were also active *in vitro* but the reverse was not true. BRIDING (above) has made an extensive study of the respiratory metabolism of filarial parasites, and his *in vitro* methods were used as an aid in screening new compounds. Many substances based on the model of 348 above and others of widely different constitution were studied as well as non-cyanine dyes with structural features similar to cyanines. None of the latter was active *in vivo* but some showed activity *in vitro*. The data given must be studied in the original. The authors consider that any substance active against filariasis in man would show both *in vivo* and *in vitro* activity against *L. carinii*. On that basis a number of substances have been selected for further study with a view to trial in the human disease. J. D. FULTON

VARGAS L. Notas sobre la oncoercerina. VII. Infección experimental de 5 mm. mm (Larva) mang. -ri con *Onchocerca volucri*. Notas on Oncoercerina. VII. Experimental Infection of 5 mm. mm (Larva) mang. -ri with *Onchocerca volucri*. Rev. Inst. Sal. Publ. y E. Formales Trop. Mexico, 1948 Dec v 9 No. 4 372-11

The English summary appended to the paper is as follows:—

A 5 mm. mm (Larva) mang. -ri female obtained by culture of *Onchocerca volucri* made in the town of Los Remedios Méx. at 2,645 mts. above the sea level, but

in the Laboratory of Mexico City a carrier of *Onchocerca volvulus* microfilariae, 124 hours after the infective meal the simulum showed sausage forms developing in the muscles of the thorax "

HIRCHCOCK, Dorothy J Artifacts in Transparent Adhesive Tapes used for Perianal Pinworm Swabs *Amer J Trop Med* 1949, Mar, v 29, No 2, 247-8, 2 figs

" A microscopical study was made of two brands of transparent adhesive tapes for artifacts resembling *Enterobius vermicularis* eggs. Very few artifacts, other than bubbles, simulating pinworm eggs were found "

BOYCOTT, J A An Improved Swab for the Detection of Threadworm Ova *J Clin Path* 1949, May, v 2, No 2, 149

The author describes a device for the detection of ova of *Enterobius vermicularis* which has been found to have some advantages over N I H swabs [this *Bulletin*, 1937, v 34, 878]

It consists of a wooden tongue depressor (6 in \times $\frac{3}{4}$ in) over the end of which is doubled a strip of Cellophane (3 in \times 1 in) held in place by several turns of a rubber band

The swab is rubbed along the peri-anal folds, preferably as soon as the patient awakes in the morning the pressure used should be just short of causing pain

The swab is placed in a paper envelope (about 2 in \times 4 in), bearing the patient's name In the laboratory, the Cellophane is opened out and attached to a slide by means of a drop of Canada balsam The areas showing epithelial and faecal debris are picked out microscopically with a $\frac{3}{8}$ in lens

The single crease in the Cellophane, the strength and the simple packing are improvements on the original N I H swab H J O'D Burke-Gaffney

HAND, E A & CRISWELL, R H Otitis Externa due to *Oxyuris vermicularis* *Arch Dermat & Syph* 1949, Feb, v 59, No 2, 249-50

The authors discuss some of the literature relating to external otitis and conclude that the rôle of fungi in the causation of this condition has been greatly overstressed Injudicious or excessive topical treatment of seborrhoeal, eczematous and related affections of the external auditory canal is a common cause of otitis externa and picking and scratching of the ears is a frequent habit in those affected

Enterobius vermicularis may be found occasionally in the nose and ears of persons in the tropics, infection being presumably carried by the nails The present case refers to such an infection It relates to an ex-officer of the U S Army who complained of pruritus and discharge from both ears This had been noticed first in Burma some months previously The patient had had no treatment and no history of previous ear affections or of pruritus ani

On examination, the ear drums were intact and hearing was normal There was scaling and erythema around the external auditory meatus and up the canals In a slight sero-ceruminous discharge from the ears, microscopical examination revealed many motile threadlike worms which were determined to be " a genus [*sic*] of *Ox. vermicularis* " No ova were found in the discharge, under the nails or around the anus No adult worms were found in the stool

The condition cleared up on cleaning of the ears with alcohol and the application of a few drops of 20 per cent benzyl benzoate in calamine lotion twice daily for two weeks

ERHARDT A. Einige grundsätzliche Bemerkungen zur Wirkung von Oxyurenmitteln. [Fundamental Points on Measures for dealing with Enteroblasts.] *Deut. med. Woch.* 1949 Apr 1 v 74 No. 15 406-7

This is a contribution to Professor Rodenwaldt's 70th Birthday Festschrift. The author divides his subject into (i) aetiological action, i.e., drug treatment of the infesting worm (ii) prophylaxis. Under the first he mentions in particular oil of chenopodium, but notes that it is not sufficient merely to examine the faeces soon after and, finding no ova, to report the patient as cured. The worms may remain unexpelled for some time and search must be assiduously carried out for 4-5 weeks to prove death of the worms and even longer (up to 3 months) before one can be certain that all have been expelled. They may have lodged in the appendix and the drug may not have reached them in their hiding-place.

As for prophylaxis we must guard against auto-infection *per os* and also by inhalation of ova in dust. Treatment of the patients and so drying up the source of supply as it were and local application of some ointment to avert the itching and prevent infection of the fingers are obvious means for attaining this end.

CARTER J. R. Plasma Cell Hyperplasia and Hyperglobulinemia in Trichinosis. The Duration of Larviposition. *Amer. J. Path.* 1949 Mar v 25 No. 3, 308-23 6 figs. on pl. 30 refs.]

"Viable adult trichinae including gravid females were observed microscopically in the small intestine of a fatal case of human trichinosis 115 days after the onset of symptoms. The patient was continuously hospitalized and under close observation for 87 days. Remission although remotely probable was considered to be adequately excluded. The period of persistence of living adult trichinae in the human intestine is the longest thus far recorded. The continued release of larvae over relatively long periods of time is of considerable significance from a clinical, prognostic and therapeutic point of view. The degree of infection as determined by counts with the trichinoscope is considered moderate to heavy.

"The diffuse plasmacytosis with associated hyperglobulinemia is considered to constitute an unusual, if not unique cellular response to trichinosis.

DEFICIENCY DISEASES

KATZ H. D. A Concept of the Etiological Complex of Deficiency States with especial consideration of Conditions. *Milbank Memorial Fund Quarterly* 1949 Jan. v 27 No. 1 5-97 3 figs. 48 refs.]

In this comprehensive examination of the aetiology of deficiency states the author emphasizes that nutritional deficiency is not necessarily synonymous with dietary deficiency. In the past much emphasis has been laid upon the relationship of diet to disease to the exclusion of sufficient consideration of all the other environmental conditions both internal and external, which govern the adequacy of nutrition at a cell level.

Many external environmental factors socio-economic (physical and chemical) in addition to simple dietary intake affect the adequacy of tissue nutrition and the internal environment may affect this adequacy through impairment of many metabolic channels and changes in many functions and reactions. As the author summarizes his able essay "It is possible that disease of

unknown cause may be nutritional in nature is not to be forthwith dismissed because it apparently is not the effect of dietary deficiency alone, rather, this contingency can be examined on broader aetiological grounds"

Dean A Smith

CORKILL, N L Dietary Change in a Sudan Village following Locust Visitation
Africa 1949, Jan, v 19, No 1, 1-12, 5 figs on 4 pls & 1 map [18 refs]

The population of the Fung area of the Anglo-Egyptian Sudan normally cultivate millet, cow-peas and sesame seed as subsistence crops, and they barter animals and milk products with cattle-owning nomads. In addition they have a number of valuable wild fruits at their disposal, and consume a considerable proportion of their millet fermented as beer. Their diet, as assessed in a series of seasonal surveys, in normal years, is entirely adequate by any standards.

In 1938 their crops were destroyed by locusts to a very great extent, and for the ensuing 8 months they were very short of their normal foods and used bush products increasingly. The main foods upon which they depended were guinea-fowl, gingerbread nut (*Hyphaene thebaica*), the desert date (*Balanites aegyptiaca*) and the cluster yam (*Dioscora dumetorum*). Evaluation of this partial famine diet indicated a small, possibly unimportant, deficiency in total calories, an almost adequate intake of fat, salt, nicotinic acid and ascorbic acid, but important deficiency of vitamins A, B₁ and riboflavin.

It was possible to carry out a clinical examination of the community in the famine area after 4 months of famine and after 8 months, at which time the Government stepped in with famine relief measures. After 4 months there was no evidence of major deficiency disease, but after 8 months all complained of pain in the belly and a sense of distension. These signs and symptoms suggest either poisoning from desert dates and dioscorine or vitamin B₁ deficiency, or possibly both. One case only showed neurological manifestations characteristic of dry beriberi, and thus, taken with the prevalence of digestive disturbance, abdominal distention and the presence of a buccal frieze, was considered to suggest that the population was on the brink of an outbreak of dry beriberi. [Some workers would not agree with the author's interpretation of buccal frieze as suggestive of beriberi.]

It is concluded from this most interesting series of observations that much can be done to insure against nutritional catastrophe from locust visitations, by growing a reserve root crop such as manioc, and by growing ground nuts.

SING, K G Nutritional Survey in Gandhi Nagar Camp, Jullundur *J Indian Med Ass* 1949, Jan, v 18, No 4, 96-9

A clinical nutritional survey was carried out upon 6,000 refugees from Western Pakistan, evidence of frank deficiency was found in 83 per cent. Enquiry indicated that the diets of these refugees had, at their homes, been satisfactory and that deficiency had only arisen in transit. Incidence was higher in adults than in children and in men than in women. The outstanding manifestations were those of deficiency of B complex factors, especially riboflavin, though cases of vitamin A deficiency and scurvy were seen.

Treatment of established cases with vitamin preparations was generally rapid and successful. Strong recommendations are put forward for improving the camp diet, including the use of germinated beans, nuts, vegetables, eggs and liver.

THOMSON F. A. Dietary Deficiencies in Children in the Island of Viti Levu. *Fiji Trans. Roy Soc Trop Med & Hyg* 1949 Mar v 42, No. 3, 48-52, 8 figs. on 4 pls. [21 refs.]

In the Island of Viti Levu Fiji, urbanization is rapidly spreading and there is a change from the traditional diet to a preference for sophisticated foods and tinned store-goods. White bread, sweet tea and large quantities of sugar are becoming the staple diet of most of the smaller children from weaning time.

A clinical survey of over 7 000 school and pre-school children carried out in 1947 has shown the effect of this change on the physical status of the children.

There was found no evidence of real starvation, the diet being apparently sufficient in calories, but there was evidence of deficiency of protein, vitamin A, factors of the B complex and seasonality of vitamin C. The most marked changes were found in the teeth and it was in the 5 to 8 years age group that the highest proportion (65 per cent.) of children showed these changes.

The earliest changes seen were defects of enamel with roughening and pitting which appeared to advance with discolouration and frank caries.

The changes attributable to vitamin A deficiency, mainly phrynodermia and xerophthalmia with Bitot's spots, responded well to treatment with cod liver oil and the scorbutic gums disappeared in the fruit season. Verrows of the skin was very common.

A serious aspect of the deficiencies discovered, though some of them are themselves of comparatively little consequence, is that they indicate a rapidly deteriorating diet in an area where good food is readily obtainable, particularly fish and fruit, and that they are undoubtedly associated with less evident and possibly irreversible changes and with lowered resistance to other diseases.

It is interesting to note that Gilbertese children, whose traditional staple diet of coconuts and fish had not suffered changes of sophistication, showed none of the effects recorded on Viti Levu.

[There is a minor confusion of terminology. The term *chilous* is usually now restricted to lesions of the vermillion of the lips, and the term *perlé* is used to describe the lesions at the angles of the mouth, synonymous with *angular stomatitis*.] Dawn A. Smith

TROWELL H. C. Malignant Malnutrition (Kwashiorkor). *Trans Roy Soc Trop Med & Hyg* 1949 Mar v 42, No. 3, 417-33, 8 figs. [Summ. & refs.] Discussion 433-47. [HIMSWORTH W. TAYLOR, McROBERT C. MCKENZIE A. CHESTERMAN C. C. SMITH D. BE. ET AL. VAPIER L. E. EARLY L. P. M. V. HARE K. P. TROWELL (in reply).]

Kwashiorkor has now been reported from many parts of the tropical and sub-tropical world, and there are indications of its occurrence in Southern Europe. It goes under many names and its presenting clinical features vary, but workers are increasingly in agreement that the essential features are growth failure, oedema, fatty liver and lowered plasma albumin, while commonly associated deficiency lesions include depigmentation of skin and hair, dermatous lesions of mucocutaneous junctions and diarrhoea.

The basic aetiology is becoming more evident: the disease starts at the time of weaning and is associated with low protein relative high carbohydrate diet. Weaning on to starchy gruels made from various cereals with no other source of protein, is common practice in many areas. There can be little doubt that the condition is one of nutritional deficiency of proteins, but this does not necessarily imply that the defect is dietary. We undoubtedly occur on a basis of pure dietary deficiency but parasitic, helminth and bacterial infections and infestation commonly accentuate or even cause the condition.

The pathology of the liver was studied by biopsy in 161 cases at Mulago Hospital, Uganda, and the sequence of changes has been traced from initial fatty infiltration through periportal fibrosis to diffuse cirrhosis of the Laennec type. Atrophy and fibrosis in the pancreas, and changes in the salivary glands have also been found.

Anaemia in uncomplicated cases is usually mild in degree, and normocytic and orthochromic in type. However, when there is heavy infection with malaria or hookworm the anaemia may be severe, and constant blood destruction and attempted regeneration produce high degrees of reticulocytosis and apparent macrocytosis.

Successful treatment depends on the administration of sufficient readily-available protein, milk proving more effective than meat or liver, and the careful eradication of all infections and infestations.

The author concludes that this disease, based either on dietary imbalance, heavy parasitization or a combination of the two, affects the majority of African children in some degree, and that its results, in non-fatal cases, lead to impaired development, subnormal function, diminished resistance to intercurrent disease and premature senility and death.

[The author has devoted many years to the study of this condition and contributed greatly to our understanding of it. This authoritative and well-balanced review is important and valuable. There is a comprehensive bibliography. See also this *Bulletin*, 1948, v 45, 633, 635, 724.]

The discussion was mainly centred on the interplay and relative importance of malnutrition and infection in the aetiology in Kwashiorkor.

WATERLOW made a valuable contribution in suggesting that organs most active in handling protein are most vulnerable to protein deficiency. Such organs are the intestines, pancreas and liver, and the concept of an initial defect of enzyme formation, with consequent defect of digestion and absorption, would explain much of the complex clinical picture and the difficulties of treatment.

Dean A. Smith

HARTZ, P. H. **Pancreatic Atrophy in Infants with Fatty Liver.** *Documenta Neerlandica et Indonesica de Morbis Tropicis*. Amsterdam 1949, Mar., v 1, No 1, 41-9, 6 figs. [15 refs.]

In the disease of infants and young children now widely recognized and known as kwashiorkor or malignant malnutrition, and characterized by liver damage, hypoproteinaemia and anaemia, pancreatic changes have been described by several workers. DAVIES [this *Bulletin*, 1948, v 45, 633] in Uganda found fibrosis in many and atrophy in a few cases, WATERLOW [*ibid.*, 724] in the West Indies found atrophy of acinar cells, while MAGHALHÃES CARVALHO [*ibid.* 635] in Brazil and VÉGHÉLYI (*Lancet*, 1948, Mar 27, 497) in Buda-Pest found diminution in pancreatic enzyme secretion.

Microscopic examination of the pancreas was performed on 14 infants who had died with fatty infiltration of the liver. It was possible to obtain the post-mortem material very fresh. There was advanced atrophy of the acinar cells in all cases. The islet tissue appeared normal. The fibrosis, described by Davies in older children, was not seen in these babies. In a series of controls who died of intestinal or respiratory infection, or of undernourishment without severe fatty infiltration of the liver, no such severe pancreatic atrophy was found.

Although fatty infiltration of the liver is relatively common in Curaçao (49 cases in 249 autopsies) the "fully developed syndrome of fatty liver disease" [presumably characterized by the skin, hair and muco-cutaneous-junction lesions of associated avitaminoses—though this is not stated] is rare.

The author concludes that the primary lesion of this disease is in the pancreas and that fatty infiltration of the liver is secondary to it.

[Another interpretation of such findings has been put forward and was summarized in a leading article in the *Lancet* 1949 Jan. 29 188. Most workers are agreed that the main aetiological factor in the disease is protein deficiency in the presence of relative excess of carbohydrate intake. It is suggested that the organs most active in handling protein are also most vulnerable to protein deficiency—such organs are the pancreas, intestinal tract, liver and salivary glands, in all of which lesions have been described. Moreover much of the protein utilized by the gut, pancreas and salivary glands goes into the formation of digestive enzymes, the production of which is known to be impaired in fatty liver disease. Thus it may be considered, rather than that disease in one organ is secondary to disease in another, that there is based on deficiency of total protein or some protein components, failure of and damage to all those organs which utilize protein most rapidly. As these organs are mainly concerned with digestion and absorption this concept would explain the complexity of the clinical picture, the readiness with which secondary deficiencies occur, the variability in the results of treatment and the tendency to the establishment of a vicious circle.]

SPRUE.

STEFANINI M. The Diagnosis and Pathogenesis of Tropical Sprue. *Acta Med Scand* 1949 Mar 31 v 133 No 2, 113-29, 1 Ag. [60 refs.]

This paper epitomizes a review of the sprue syndrome carried out in British India during the war on almost 6,000 cases of tropical sprue occurring among military units. The fundamental symptoms are represented by a particular defect of intestinal absorption which is especially detectable in the case of fats.

The progression of the case is closely related to intestinal malabsorption, and can be divided into three successive stages—a first in which the initial signs of impaired intestinal absorption predominate, a second in which secondary deficiency signs set in, and a third in which with the appearance of macrocytic anaemia the patient presents the complete picture of tropical sprue. The first two stages include also the mild and incomplete forms of the sprue syndrome.

In the author's experience the disease was found as frequently in Indians as in Europeans.

A partial defect of intestinal absorption of fats, which is usually detected earlier and more easily than that of any other dietary constituents, represents the basis for the diagnosis. The "fat balance" technique which the author describes probably represents the best method of study of intestinal absorption. Chemical analysis of the faeces usually shows high stearic/oleic with sphingomyelin/split fat ratio and soaps/split fat ratio higher than normal. The greatest part of split faecal fat in sprue appears to be present as soaps. Dietary deficiencies constitute the most important factor among those leading to the development of tropical sprue, but by itself it is not sufficient to explain all the peculiarities of the series of cases described in India during the war, such as the epidemic appearance in a particular period of the year and the sudden explosive high incidence among military units shortly after their transfer to special areas. It would appear that tropical sprue occurs epidemically whenever and wherever favourable seasonal, local and climatic conditions exist. P. Manon-Baker

An account of 3 cases

HAEMATOLOGY

WROBLEWSKI, F, WEINER, M & SHAPIRO, S A Simplified Procedure for Blood
Cell Counts and Haemoglobin Determination *J Clin Path* 1949, May, v 2,
No 2, 138-40

TAYLOR, G F, CHHUTTANI, P N & KUMAR, S The Meat Ration and Blood
Levels Investigation of Indian Soldiers in Persia and Iraq, 1944 *Brit.
Med J* 1949, Feb 5, 219-21

Haematological investigations were carried out among Indian soldiers in Shaiba (Iraq) in 1944. The men were engaged on heavy pioneer work (44 hours a week) and were on Army rations of over 3,000 calories with over 80 gm of protein. Random samples of 40 meat-eaters and 42 vegetarians were taken for the investigations. The only difference in the rations, which consisted of rice or atta, dāl, ghee, tinned milk, onions, potatoes and fresh leafy vegetables (when available), was that in the former group a ration of 6 ounces of fresh mutton (with bone=4 ounces without bone) was given on 5 days a week.

The means of the red cell counts and of the haemoglobin estimations were significantly lower among the vegetarians, 4.67×10^6 and 14.32 gm, compared with the meat-eaters, 5.55×10^6 and 15.44 gm. The MCV was significantly higher 109.48 cμ in the vegetarians than in the meat-eaters, 96.33 cμ. The MCHC in both groups was low, 28.54 and 28.32 per cent (indicating a common iron deficiency). Eight of the vegetarians had red cell counts below 4×10^6 and two showed marked anaemia, below 3×10^6 .

The sternal marrow showed significantly higher percentages of megaloblasts, erythroblasts and macroblasts among vegetarians.

"There was no clear clinical difference between the two groups." "The vegetarians could often be distinguished by a tired look." Associated infections, malaria, bacillary dysentery and hookworm, were present in both groups. Three severely anaemic men from the vegetarian group were admitted to hospital for thorough investigation. In these no complicating infections were found although one had recently had bacillary dysentery. On the ordinary unit diet and rest in bed, the blood pictures of two of these men returned to normal within four weeks.

The authors conclude that, since the only constant aetiological factor in the production of the defective haematological state in the vegetarians was the absence of the weekly ration of 20 ounces of mutton, under conditions of hard physical work, diet alone unassisted by coincident infections, can produce macrocytic anaemia.

L E Napier

CHHUTTANI, P N A Report of 46 Cases of Anaemia in the Punjab with special reference to Nutritional Macrocytic and Addisonian Anaemia *Indian Med Gaz* 1948 Nov, v 83, No 11, 503-13 [14 refs]

The aetiological varieties and types of anaemia encountered in a series of forty-six cases in the Punjab are recorded. In 40 of the 46 cases studied, the

anaemia was classed as dyshaemopoietic. Of these 21 were cases of iron-deficiency anaemia and 14 deficiency of the haemopoietic principle. Of the latter 7 were nutritional macrocytic anaemia and 2 Addison's pernicious anaemia—these last 9 cases form the material on which this paper is based.

Two cases of nutritional macrocytic anaemia not complicated by malaria or splenomegaly had hyperbilirubinaemia comparable to that seen in Addisonian anaemia. These cases had marked anisocytosis comparable to that expected in Addisonian anaemia. This was regarded to be the possible explanation of the unusual finding of hyperbilirubinaemia.

"In these two cases the Price-Jones curves were indistinguishable from those seen in Addisonian anaemia.

"They fulfilled textbook criteria of Addisonian anaemia. Positive clinical evidence against a possible nutritional aetiology was forthcoming. Both were regarded to be instances of true Addisonian anaemia.

Differential diagnosis of nutritional macrocytic and Addisonian anaemia is discussed and it is concluded that the absence of intrinsic factor in the gastric juice of our suspected patients must be proved before the existence of Addisonian anaemia in India can be incontrovertibly established. A simple method to carry out this proof is suggested.

SMITH C. H. Detection of Mild Types of Mediterranean (Cooley's) Anaemia. *Amer J Dis Children*. 1949 Apr., v 75 No 4 505-27 8 figs. (1 map) [Refs. in footnotes.]

Cooley's anaemia is confined mainly to persons of Greek-Italian (principally Sicilian) and Syrian origin and the parents and siblings of patients with severe forms of the anaemia may show clinical and haematological evidence of the disease varying from this trait to a moderate form of anaemia. There are over 5 million persons of these origins in the United States and a recent investigation suggested that 1 in 25 of the Italians in the city of Rochester N.Y. had a mild form of the disease.

The present report is based upon the investigations in 47 families with Cooley's anaemia. Clinically persons with the trait or a mild form of the disease may show none of the classical features the facies, the skeletal changes, cardiac enlargement and murmurs, and pains in the joints but in mild cases there may be pallor and splenomegaly.

The changes in the blood on which the diagnosis depends are as follows:—

Blood smear and blood count show hypochromic macrocytes, basophilic stippling, oval and target cells, polycythemia.

Morphologic changes in erythrocytes as far in excess of the degree of anaemia.

Resistance of the red cells to haemolysis in hypotonic solutions of sodium chloride is increased.

"Iron or other forms of antianaemia therapy fail to restore normal blood levels."

Figures are given showing the incidence in the 47 families. In 33 families both parents were examined—in every instance of a severely anaemic child both parents had a mild form of the disease or showed the trait and when one parent only was examined, that parent showed the trait. In every instance where there were siblings, one or more were affected. In every instance of a mildly anaemic child or a child with the trait at least one parent was affected, and when there were siblings at least one was affected. The first-born child most frequently escaped the disease or the trait.

Of the various names suggested the author prefers Mediterranean (Cooley's) anaemia with the qualifications mild, moderate or severe.

The author concludes with a plea for a more thorough investigation of the disease, and especially of mild forms, in the recognized countries of origin of this disease and in other countries from which severe cases have been reported

LONDON, I M SHEMIN D, WEST, R & RITTENBERG, D Heme Synthesis and Red Blood Cell Dynamics in Normal Humans and in Subjects with Polycythemia Vera, Sickle-Cell Anemia, and Pernicious Anemia *J Biol Chem* 1949 May, v 179, No 1, 463-84, 9 figs [27 refs]

DICKSTEIN, B, LANDMESSER, W E, Jr, LOVE, W E, WILSON, T H & WOLMAN, I J The Osmotic Resistance of Human Erythrocytes in Normal, Carrier and Anemic States with special reference to Changes due to Age, Race, Sickle-Cell Anemia, Mediterranean (Cooley's) Anemia and Congenital Hemolytic Icterus *Amer J Med Sci* 1949, Jan, v 217, No 1, 53-61, 6 figs [28 refs]

The authors adopted a method of measuring osmotic resistance of erythrocytes which was suitable for photographic reproduction. The solutions that they used were 0.18 M glycerol in 0.36 per cent NaCl, 0.24 M thiourea in 0.18 per cent NaCl, 0.47 per cent NaCl, and 0.36 per cent NaCl. They tested the osmotic resistance in 170 normal and 90 abnormal persons.

They found that in normal white children up to 10 years of age the osmotic resistance was greater than in white adults, but that in negroes this difference did not exist. The normal resistance of the negro is greater than that of the white man. These differences make it essential that control examinations should always be made with the blood of persons of a comparable age and colour group.

In sickle-cell anaemia the osmotic resistance is higher than in the normal negro, in the sickle-cell trait it shows an intermediate position.

In Mediterranean (Cooley's) anaemia, the osmotic resistance is greater than in the normal person, in the carrier (person showing the trait) the erythrocytes show a slightly greater degree of resistance than in the patient with the anaemia.

In congenital haemolytic icterus a markedly lower degree of resistance is shown, the method detects increased fragility in cases in which the ordinary methods do not.

The osmotic resistance was tested in several other anaemic states including iron-deficiency anaemia and pernicious anaemia and found to be within normal limits.

L E Napier

CALLENDER, Sheila T E, NICKEL, J F, MOORE, C V & POWELL, E O Sickle Cell Disease studied by measuring the Survival of Transfused Red Blood Cells. *J Lab & Clin Med* 1949, Jan, v 34, No 1, 90-104, 8 figs [15 refs]

Employing the DACIE and MOLLISON (*Lancet*, 1943, May 1, 550) technique, the authors studied the time of survival of red cells in sickle-cell disease. Normal cells transfused into subjects with sickle-cell anaemia survived normally. Cells from patients with sickle-cell anaemia transfused into normal subjects or into another patient with sickle-cell anaemia showed a shortened average time of survival, the curves showed a sharp fall, indicating the rapid destruction of half or more of the cells within 10 days, followed by a slow decline to the zero line which was reached in about 60 days indicating a much slower destruction of the remaining cells.

Cells from a healthy subject with the sickling trait transfused into normal subjects or patients with sickle-cell anaemia survived normally.

Oxygen inhalation (70-80 per cent.) slowed the rate of destruction of sickle-cell anaemia cells in one subject with sickle-cell anaemia but not in another. The survival time of trait cells in a cyanosed boy with congenital heart disease was normal.

The findings indicate that the defect in sickle-cell anaemia is inherent in the red blood cell. There is evidence to suggest that sickling is not, as has been thought, a function of age of the cell but that the cells in sickle-cell anaemia vary constitutionally in their liability to sickle. It is suggested that the difference between the anaemia and the trait is qualitative and not simply one of degree.

L. E. Asper

WILLIAMS, A. W. & MACKAY, J. P. Rapid Determination of the Sickle Cell Trait by the Use of a Reducing Agent. *J. Clin. Path.* 1949 May v " No. 2, 141-2.

There is need for a simple and accurate technique for determining the sickle cell trait which will serve for rapid exclusion of sickle-cell anaemia in practice and which can be used for uniform survey work. The authors refer to the deficiencies of the sealed wet preparation and also to various improved methods but some of the latter are complex and not suitable for the clinical sick-room. In 1928 HARRY [this Bulletin 1928 v 3 1001] and later SHERMAN (*Bull. Johns Hopkins Hosp.* 1940, v 67 309) showed that sickling only occurs in those having the sickle cell trait when corpuscular haemoglobin is in a reduced or dissociated state—the change is accelerated by a low pH.

The authors sought an acid reducing agent which would cause rapid dissociation of oxyhaemoglobin and hence reveal sickling in a short time without causing damage to the red cell in isotonic solution. Sodium hydrosulphite (dithionite $\text{Na}_2\text{S}_2\text{O}_4$) was selected and was found to fulfil these conditions admirably.

A 2.1 per cent. aqueous solution (in freshly boiled distilled water allowed to cool) was found to be isotonic and to have a pH of 6.4. Sodium hydrosulphite is a powerful reducing agent which decomposes in moist air—a solution will not keep indefinitely and the 2.1 per cent. solution is therefore made once weekly and kept in small bottles sealed with liquid paraffin. A tube should be discarded at the end of the day on which the seal has been removed.

For the test a drop of the isotonic sodium hydrosulphite solution is taken up in a fine Pasteur pipette and about one-sixth of this quantity of blood is drawn up in apposition to it. The whole is expelled on to a clean slide and rapidly mixed. The slide is inverted on to a cover slip (which need not be sealed) and examined under the 15 in. objective. The same pipette may be used for any number of patients, if it is rinsed in saline.

If the sickle-cell trait is present sickling occurs in 3 to 15 minutes and rapidly becomes generalized—it usually appears earliest in cells near the edge of the coverslip. If no sickling occurs after 20 minutes the blood may be pronounced negative for the sickle-cell trait. Sickling never occurs in normal blood (after half an hour red cells may, however, become crenated).

This technique was compared with the wet sealed preparation (read at 48 hours) in the case of 100 African schoolboys. There was complete agreement between the methods. The new technique always gave the result in 20 minutes while the sealed wet preparation sometimes gave doubtful results after 24 hours. (The numerical results will be published separately as part of a survey.)

The authors consider this technique to be superior to other in current use as regards speed, simplicity and reliability.

In a footnote, reference is made to the work of THOMAS and STETSON (*Bull Johns Hopkins Hosp*, 1948, v 83, 176) which was noticed by the authors since their paper was sent for publication. The authors quoted found a saturated solution of hydrogen sulphide to be the most reliable and rapid agent for demonstrating sickling, among sulphhydryl compounds which they tried. The present authors believe that sodium hydrosulphite has practical advantages as to odour, stability and preparation of the solution.

SCOTT, R B, CRAWFORD, R P & JENKINS, M. Incidence of Sicklemia in the Newborn Negro Infant. *Amer J Dis Children* 1948, June, v 75, No 6, 842-9, 1 fig

The blood of 262 negro infants selected at random, were tested for the sickling trait by the coverslip method. One drop of blood in isotonic saline was placed under a coverslip surrounded by petrolatum and examined after 24 to 48 hours at room temperature. On the first day of life, 7, or 2.6 per cent, gave a positive result. Of the total, 133 were tested again on the third day of life of which 3, or 2.2 per cent, were positive, and 129 were tested on the fifth day of life of which 6, or 4.6 per cent, were positive. Two that gave a negative test on the first day became positive by the fifth day, so that a total of 9, or 3.4 per cent, showed the sickling trait in varying degrees. In every case a blood count showed the haemograms to be within the normal range.

Two hundred and nine older children were tested, of these 16, or 7.6 per cent, showed the sickling trait. Blood counts were done in 7 of these children and 2 were found to be anaemic and were diagnosed as active sickle-cell anaemia.

Three children showing the trait in infancy were tested again at 7, 11 and 17 months, and in all these cases the percentage of sickling was increased, from 20, 10 and 40 to 29.2, 37.0 and 85.8 per cent, respectively. L E Napier

VENOMS AND ANTIVENENES

AHUJA, M L & BROOKS, A G. Mode of Action of Russell's Viper (Daboia) Venom. *Indian J Med Res* 1948, Apr, v 36, No 2, 173-80, 1 graph.

"1 Experimental evidence strongly supports the view that daboia venom consists of only one fraction of any pathological importance, i.e. a strong blood-coagulant fraction.

"2 Histological examination of tissues of animals dying of daboia-venom poisoning show that there is extensive deposition of fibrin in capillaries. This deprives the circulating blood of its fibrin content rendering it incoagulable. Such incoagulable blood is itself a coagulant proving that no 'anti-fibrin ferment' exists in the venom."

GRASSET E. Standardization of the Cobra (*Naja flava*) Antibody. A Comparative Study by the Method of Assay at various Levels and by the Selected Antivenene Single-Level Method. *Bull World Health Organization* Geneva 1949, Mar, v 2, No 1, 69-83, 1 fig

SERGEANT, Et. Étude comparative du venin de scorpions mexicains et de scorpions nord africains [Study comparing the Venom of Mexican Scorpions with that of North African Scorpions]. *Arch Inst Pasteur d'Algérie* 1949, Mar, v 27, No 1, 31-4 1 fig

The authors method of studying scorpion venom is probably known to readers of this *Bulletin*, but may be briefly recapitulated. The telson is removed,

dried at 37°C. and kept in the dark in a sealed tube. For testing it is ground in a mortar and the resulting powder is macerated for several hours in 0.9 per cent. sterile saline with glass beads and repeatedly shaken. White mice are the experimental animals used and the injection is made subcutaneously. The m.l.d. for mice of 20 gm. of the venoms of the North African scorpions is

<i>Prionurus australis</i>	1/20 of a telson
<i>Prionurus amoenus</i>	1/5 " " "
<i>Prionurus hoggerensis</i>	1/1 " " "
<i>Buthus occiduus</i>	1 " " "
<i>Hottentotta gentili</i>	1 " " "
<i>Scorpio maurus</i>	7 telsons

The first-named is thus much more toxic than the others.

Two Mexican scorpions *Centruroides noxius* and *C. limpidus limpidus* have been studied in the same way. Their telsons are much smaller than that of *P. australis* about half the length and breadth and one-third to one-fourth the weight. The fatal dose for the white mouse is in each case one telson (8 mgm.). *C. noxius* is rather the more toxic of the two $\frac{1}{2}$ telson (4 mgm.) kill one out of two mice whereas with $\frac{1}{2}$ (2 mgm.) and even $\frac{1}{4}$ (1 mgm.) of *C. limpidus* both survive. The fatal dose of *P. australis* is 1.5 mgm. as compared with 8 mgm. of *C. noxius* or *C. limpidus*.

Next the cross-effects of the antivenins (prepared from the horse) were compared. The *P. australis* antivenin saved 9 out of 10 mice injected with an otherwise fatal dose of the venom of this scorpion or of *Buthus occiduus*. A boy of 8 years was stung by the latter and in a few minutes became comatose; he was saved by a subcutaneous injection of 20 cc. of *P. australis* antivenin.

Similar tests with Mexican scorpion antivenins showed that they were much more potent against the Mexican venoms than was *P. australis* antivenin and, vice versa, *P. australis* antivenin was much more potent against its own venom than were the Mexican antivenins although the Mexican venoms were much less toxic than the North African species. With the *C. noxius* venom and Mexican antivenin 31 mice survived out of 50 with *P. australis* antivenin only 13 out of 50 with *P. australis* venom and Mexican antivenin 25 out of 50, whereas with *P. australis* antivenin 85 per cent. survived 47-48 out of 50. There is therefore some fundamental difference between the North African and the Mexican scorpion venoms. H. Harold Scott

DEL FORT, E. C. Ressemblances et différences dans les actions physiologiques des venoms des scorpions. [Similarities and Differences between the Physiological Actions of Scorpion Venoms.] Arch. 1 st. Pasteur d'Algérie 1949 Mar., v 77 No. 1 35-R. [13 refs.]

The author states that the actions of different scorpion venoms are very similar. Injections of large doses of *Centruroides limpidus* venom for example which is the least toxic of the Mexican scorpion venoms produce the same effects as the more toxic *C. noxius* and *C. suffusus*. EPGENT has shown (see the preceding abstract) that the venom of *P. australis* and *C. noxius* are antigenically distinct, although according to the present author the physiological effects are the same—fibrillation, clonic convulsions, rise of arterial pressure, salivation and paralysis of the movements of respiration. He shows that the muscular movements are due to the action on the motor neurones and not to action on the muscle fibres themselves for though the convulsive movements are produced by direct contact of the venom on the muscles, the series is intact; there is no such movement if the nerves to the muscle are severed. The rise of blood pressure is similarly due to the action of the venom

on the spinal cord, on the sympathetic preganglionic neurones of the vessels and the suprarenals. Some organs deprived of their nerve-supply show vasoconstriction which is not seen when the suprarenals are extirpated. The respiratory paralysis is of central origin and is preceded by a long period of irregularity in depth and rate of respiration. Hitherto the interpretations have been varied, some attributing the effects to peripheral action, others to bulbar, others again to neuro-muscular blocking.

DERMATOLOGY AND FUNGUS DISEASES

FOX, H. Cutaneous Manifestations of some Tropical Diseases. *Arch Dermat & Syph* 1949, Feb, v 59, No 2, 127-44, 5 figs

This is a lecture delivered at the Ninety-seventh Annual Session of the American Medical Association in Chicago in June, 1948.

The author talks of certain tropical diseases with skin lesions which he had met with among soldiers and sailors returned from the late World War. He deals with five only: yaws, pinta, bartonellosis (*verruca peruviana*), cutaneous leishmaniasis and leprosy. He notes that 32 cases of yaws had been reported from the Army and 24 from the Navy and Marine corps. He does not say how many cases of pinta he has seen, but confines himself to general remarks on the disease and its history. Of oriental sore, 499 cases had been reported from the American Army in the Middle East, probably contracted in Persia. Of Carrion's disease six cases in the Navy and Marine Corps were reported in the war, and of leprosy 22 among veterans. This number is, unfortunately, likely to go up as cases with long incubation declare themselves.

There are excellent photographic reproductions of patients with pinta and *verruca*. [The paper contains nothing with which readers of this *Bulletin* are not familiar.]

GUIMARÃES, F. N. & RODRIGUES, B. A. O puru-puru da Amazônia (pinta, carate, mal del Pinto etc.) Contribuição ao seu estudo. [Mal del Pinto in Amazônia, Brazil.] *Mem Inst Oswaldo Cruz* 1948, Mar, v 46, No 1, 135-97, 24 figs & 1 map [107 refs]

Puru-puru, a local name for pinta, or *mal del pinto*, has been given various explanations. One that it was a disease affecting those living on the banks of the Rio Puru, others that the name is a corruption of "pirú-porú", itself a corruption of *pirera-poroc*, signifying a "skin which desquamates". The authors give a long list of those who have studied the condition down to the time when Chagas said that it and pinta were one and the same, and investigations in the last 30 or more years have served but to confirm this. They next briefly note the existence of this disease, first outside Amazônia and then in more detail the distribution within the Amazonas, particularly along the rivers Negro, Japurá, Solimões, Javari, Juruá and Purus, and a line map shows this clearly. There follows a detailed description of the clinical features with photographs of patients and photomicrographs of sections of the skin showing the lesions set up. The dyschromic lesions are of three forms: i. Papulo-squamous with severe itching, and edges well defined; ii. Maculo-squamous, larger, paler, with at times, pigmented centres; iii. Dyschromodermic maculae, with pigmentary changes more or less marked, but with little desquamation.

Epidemiological data are based on 69 cases only, hence the facts stated must be accepted guardedly if applied generally. In one district, Labrea, of 28

patients 16 were between 10 and 30 years of age whereas in another group 36 patients 18 were between 5 and 15 years. Sex plays no part of the 69 there were 34 males, 35 females. As regards race of the total 74 were blacks 19 whites 16 were Indians and 10 were mulattoes. Of 41 in Labrea and Povoado Belém 34 belonged to 8 families (but this might just as easily be explained by a common origin as to a family susceptibility). The pathological anatomy is well illustrated by tissue sections. The paper concludes with details of 47 cases. Neosalvarsan gave the best results in treatment. *H. Harold Scott*

MASSOUD C. F. I. D. The Radiological Picture of Mycetoma. (Report of a Case verified by Biopsy). *J. Roy. Egyptian Med. Ass.* 1949 Jan., v. 32, No. 1 64-8.

"1. A case of mycetoma of the foot is clinically and radiologically described. The diagnosis was ascertained by a biopsy examination.

"2. At some stages of the disease (not at the start) the radiological picture may suggest the condition. This may be seen in the reported case. The multiple cyst like areas of bone destruction etc., and the exclusion of pyogenic osteomyelitis, tuberculosis, syphilis, and malignancy suggest a condition of a fungus infection.

"3. The reported case presents a slight degree of new bone formation. This is not usual because the common findings in this condition show that it is mainly destructive.

STEWART C. B. Histoplasmosis Sensitivity in the Maritime Provinces and Newfoundland. *Canad. J. Pub. Health* 1949 Apr. v. 40 No. 4 178-82. [11 refs.]

"1. Histoplasmin tests were done on 310 Dalhousie University student most of them males.

"2. Positive reactions were observed in 4 men (1.3 per cent) all of whom had been part time residents of areas outside the Maritime Provinces or Newfoundland.

"3. No positive reactions were observed in 157 life time residents of the Maritime Provinces or Newfoundland.

ALLEN R. M. Experimental Histoplasmosis: Portal of Entry of the Fungus. *Amer. J. Trop. Med.* 1948 Nov. v. 29 No. 6 837-61.

The mode of infection in histoplasmosis is not known, but the frequent occurrence of lesions on the oral mucosa and in the lungs suggests an oral or pulmonary portal. Experimentally infection is easily achieved by inoculating cultures into susceptible animals by the venous or peritoneal routes but apparently there is no previous record of successful inoculation by the oral or nasal routes.

The author using living yeast form cultures of *Histoplasma capsulatum* attempted to infect guinea-pigs (12) and mice (36) through the alimentary system by adding suspensions of the fungus to drinking water and guinea-pigs alone through the nasal route by introducing the culture suspension through fine urethral catheter for this purpose it was necessary to anesthetize the guinea-pigs to prevent their struggles. Mice could not be used in this experiment because of their small size. Very large doses of culture were used in all experiments with the object of obtaining fatal infections.

In the oral feeding experiment 17 of the 36 mice died in less than 30 days and the remaining 18 were sacrificed between the 22nd and 36th days.

Macroscopic lesions were not shown but the fungus was recovered in culture from the organs of 70 per cent of the animals. Of the 12 guineapigs in this experiment, 4 died and the remaining 8 were sacrificed. The fungus was cultivated from the organs of 75 per cent of these animals.

In the nasal experiment, none of the 12 guineapigs died and all were sacrificed at the end of two weeks or later. By culture, 75 per cent of the animals were found to be infected.

The results of these experiments indicate the possibility of infection by the nasal and alimentary routes.

NORDEN, A. Agglutination of Sheep's Erythrocytes sensitized with Histoplasmin. *Proc Soc Exper Biol & Med* 1949, Feb, v 70, No 2, 218-20.

SASLAW and CAMPBELL [below] showed that collodion particles in suspension could be sensitized with histoplasmin and agglutinated by a *Histoplasma* antiserum. The present author, following the technique of MIDDLEBROOK and DUBOS (*J Exper Med* 1948, v 88, 521), used a suspension of sheep erythrocytes in place of the collodion particles. The optimal dilution of histoplasmin for sensitizing the cells was found to be 1:2, but undiluted histoplasmin was haemolytic to sheep erythrocytes. A 0.2 per cent suspension of erythrocytes could be more effectively sensitized than the 0.5 per cent suspension previously recommended.

Erythrocytes sensitized with histoplasmin were agglutinated by anti-*Histoplasma* rabbit sera but not by anti-*Sporotrichum*, anti-*Candida* or normal rabbit sera. Cross-reactions with anti-*Blastomyces* serum were not attempted.

In recording the tests, a positive result was indicated by the deposition of erythrocytes as a thin adherent film on the hemispherical fundus of the test tube, while a negative result was shown by a flat disc-like deposit of free erythrocytes. The serum end-titre in a positive reaction was as high as 1:1,280.

J T Duncan

SASLAW, S & CAMPBELL, Charlotte C. A Comparison between Histoplasmin and Blastomycin by the Collodion Agglutination Technique. *Pub Health Rep Wash* 1949, Mar 4, v 64, No 9, 290-94.

In a previous paper (*Proc Soc Exper Biol & Med* 1948, v 68, 559) the authors showed that a suspension of collodion particles "sensitized" with the soluble antigens of histoplasmin could be agglutinated by a *Histoplasma* antiserum. The present paper is a report of the application of this serological method to the study of the specificity of the *Histoplasma* and *Blastomyces* serum reactions. The degree of sensitizing power varied amongst the different batches of histoplasmin, and for each there was an optimal dilution which achieved the highest degree of sensitization of the collodion particles. The results of the tests showed that *Histoplasma* antiserum could agglutinate histoplasmin-sensitized collodion suspensions up to serum dilutions of about 1:160 and 1:320, and blastomycin-sensitized suspensions to a lower serum end-titre. The *Blastomyces* antisera were relatively poor in antibody and agglutinated the blastomycin- and histoplasmin-sensitized suspensions only to end-titres of 1:10 and 1:5 respectively.

So far, the results confirm the earlier findings that an intimate antigenic link exists between *Histoplasma* and *Blastomyces*, evidenced by the cross-agglutination reactions, but the serum end-titres in the homologous systems are higher than those in the heterologous systems.

KUZMA J. F. Histoplasmosis—the Pathologic and Clinical Findings. *DIAGNOSIS of the Cases* 1947 July—A 5 v 13 No. 4 335-44 [11 refs]

Report of a case in Milwaukee Wisconsin.

BASS H. E., SCHOMER, A. & BERKE R. Coccidioidomycosis. Persistence of Residual Pulmonary Lesions. *Arch. Intern. Med.* 1948, Dec., v 82, No. 6 519-28, 7 figs.

Little is known of the subsequent histories of cases of coccidioidomycosis which have not progressed to the stage of disseminated granulomatous disease and are presumed to have achieved complete recovery. The large number of infections estimated at 8000 in the United States Forces during wartime training in the endemic areas of coccidioidomycosis in the south-western part of the United States, has provided abundant material for a "follow-up" investigation. In this connexion, the authors were able to study in New York city 20 patients who had protracted residual pulmonary lesions of coccidioidomycosis and they give brief summaries of the clinical features of 13 of the cases. Radiography showed pulmonary lesions of various types e.g. nodular densities, cavities, mottled infiltrations, fibrosis, pleural effusion and calcification. The resemblance of many of the lesions to those of tuberculosis was striking and it is not surprising that the disease had, in several cases, been diagnosed as tuberculosis after the patient's return to civil life. However, these residual lesions characteristically showed no change during a period of observation of from 2 to 5 years. The diagnosis of coccidioidomycosis was based on the following evidence: (a) the history of exposure to infection in an endemic area (b) radiography which showed a pulmonary lesion, usually a solitary cavity or nodular density which remained unchanged during months of observation (c) indication of an identical lesion in the X-ray picture of the chest at discharge from military service (d) a positive coccidioidin skin reaction and (e) failure to find the tubercle bacillus. Skin sensitivity to coccidioidin tends to diminish with lapse of time and although a dilution of 1:1000 is usually sufficient to give a strong reaction in an early case, it was necessary to use the reagent at 1:100 or even 1:10 in the residual cases. The reactions also were rather weak in contrast with the strong reactions given by early cases. Despite the pulmonary lesions described, all of the patients were asymptomatic except three—one being a patient with cavity and recurrent haemoptyses, another with pleural effusion and the third with a progressively disseminating disease. In the cases with cavity there was no evidence of bronchogenic spread or of seeding to other parts of the lung field such as occurs commonly in tuberculosis.

J. T. Dukes

HEAT STROKE AND ALLIED CONDITION

O'DRISCOLL J. J. Tropical Anhidrotic Asthenia: Its Definition and Relationship to other Heat Disorders. *Arch. Intern. Med.* 1949 June 81 No. 6 700-031 1 fig. Refs. in footnotes.

Until recent times little has been known of the ill-effects which may be due to increasing impairment of sweat function arising during residence in tropical countries where malaria rubra (prickly heat) is of common occurrence.

The disorder called tropical anhidrotic asthenia is characterized by exhaustion, headache and dyspnoea associated with failure of sweating over large areas of

the body when working in the heat. Sweating may be profuse on the face but markedly diminished over those covered areas of the body where prickly heat is most commonly found. The condition is held to be due to the occlusion of the sweat ducts and the extravasation of sweat into the tissues. The paper contains a very full discussion of symptoms and signs. Details of 38 severe cases are compared with those given by other workers, in particular the cases of heat exhaustion type 2 described by LADELL *et al* in Iraq [this *Bulletin*, 1945, v 42 143].

The question of terminology for this disability due to post-malarial obstructive impairment of sweat function, as distinct from the classic heat disorders is considered in some detail. It is thought that the development of this disorder constitutes a specific form of tropical deterioration which limits the duration of an individual's acclimatization to residence in the tropics. G P Crowder

TROPICAL ULCER

ADAMSON, P. B. Tropical Ulcer in British Somaliland. *J Trop Med & Hyg* 1919, Apr v 52, No 4, 68-76 [19 refs.]

The author considers that present data show that tropical ulcers are probably caused by "Vincent's fusio spirochaetes in a host who has become susceptible to infection as a result of vitamin-B deficiency and possibly further debilitated by chronic disease and malnutrition" (BLANK, this *Bulletin*, 1947, v 44, 935). Tropical ulcers occur in Somaliland throughout the country, from the cold highlands of Laigayo to the hot and moist areas around Berbera.

In 1947 out of a total of 7,737 in-patients 999 were treated for this condition (135 being women), an unexplained feature being the relative infrequency in women as compared with men. It is probable that patients only attend a European doctor when the ulcers are very severe, or where a proper hospital lies within a convenient distance. A large number of early cases are probably attended by local practitioners, who are of the Midgan (sweeper) class. In treatment by these Midgan the ulcer is cleaned as well as possible with a rag or other material powdered bark of an unidentified *Acrothus* (Glover) called in Somali the *lilis* tree is made into a thick paste or applied dry and the whole area covered by a layer of mud which is left in position until it drops off or the patient decides to remove it. Alternatively powdered white catkins from *Leucaena glauca* Fork are used. In a personal statement to the author it was claimed that *lilis* bark cured 50 per cent of ulcers the time taken for cure not being stated.

The author draws the following conclusions —

1. Trauma was an almost constant predisposing factor.
2. No cases of tropical ulcer in females were found at Hargriss during the period of investigations (February to July 1948). The poorer classes were more likely to be affected than the richer ones. Age was unimportant except that very young children seemed to be exempt.
3. Associated diseases were not significant except to lower the general resistance and the anaemia present was considered to be merely a nutritional defect. The Kahn test may be positive in tropical ulcer.
4. There was a diminution in the plasma level of vitamin C in cases of tropical ulcer but oral vitamin C (ascorbic acid) was of no specific use. Reticulocytosis and raised blood sedimentation rates occurred.
5. In 10 per cent of cases there was a periostitis or bone necrosis which delayed healing and it is considered that the fusiform bacilli are responsible for this condition.
6. The most sensitive indicators as regards prognosis were the smears from ulcers and plasma vitamin C levels; the blood sedimentation rate and reticulocyte count were also useful guides.
7. Hospital diet was considered to be below the optimum standard and should be adjusted to a higher level of vitamin C while protein may be required to be increased. At present the only source of vitamin C is camel's milk. Officially each patient receives a pint of milk daily but in practice usually a good deal less was available. After the rains have begun the vitamin C content of camel's milk averages 2.678 mgm. per 100 ml.

(For details and results of the various laboratory investigations the reader is referred to the original paper.)

C. F. Skellern

MAGARA M. GO H., SO K. & AKIUE, T. On a New Species of Anaerobic Cocci Isolated from Tropical Ulcer. *Japanese Med J.* 1949 Aug. v. 1 No. 4 289-91 2 figs.

From 19 specimens from tropical ulcers the authors in Japan isolated an anaerobic coccus from ten. It was also isolated from two ulcers produced experimentally by inoculation of secretion of tropical ulcers into other persons. The coccus was isolated more frequently in the early stages subsequently it was possible to isolate it from almost every case.

The organism is a Gram-positive non-motile non-sporing coccus usually appearing in diplococcus form and having a diameter of about 1.5 to 1.8 μ . It is strictly anaerobic. The cultural characters are given in detail and they suggest as the authors point out, that the character of the diplococcus resembles that of *Diplococcus magnus* (Tissier and Martelli) but differs from it in producing black pigment in culture on 1% bouillon with liver pieces and also in being pathogenic to animals. Broth cultures injected intradermally into rabbits and guinea-pigs produced ecthyma and from the resulting abscesses the diplococcus was found in pure culture.

Serologically the coccus was agglutinated both by patients' serum and normal serum.

In 143 strains of cocci isolated from the female genitals and oral cavity only 1 strain of *Diplococcus magnus* was found and no cocci identical with the diplococcus now described were found.

The authors suggest that the diplococcus is rarely found except in tropical ulcer and since spirochaetes and fusiform bacilli are not confined to tropical ulcer it is suggested that this diplococcus is the essential cause of tropical ulcer. They have therefore named it *Diplococcus tropicus*. This interesting

observation merits further investigation but in view of the small series of cases and the inconclusive serological findings, the basis for giving the organism this specific name is perhaps a little uncertain] *H J O'D Burke-Gaffney*

VAN ZANTEN, T V Beenverlenging bij het ulcus tropicum [Elongation of the Leg in Tropical Ulcer] *Nederl Tijdschr v Geneesk* 1949, Feb 5, v 93 (1), No 6, 408-9

The English summary appended to the paper is as follows —

"In sufferers from low-seated ulcera tropica, the leg is often elongated. The cause is not clear. The author expects the phenomenon to disappear on the availability of better nutrition and better medical care."

HALAWANI, A Desert, Septic, or Veldt Sore in Egypt *J Roy Egyptian Med Ass* 1944, Aug, v 27, No 8, 214-36 [19 refs] [Recd 13 Dec, 1948]

During 1943 and 1944 there were outbreaks of ulcer in several towns in Egypt, including Port Said and the author saw approximately 500 cases. They were of the type usually called septic, desert or veldt, some were very septic and assumed a phagedaenic character. The former were "punched out and circular in outline with undermined edges and thickened margins", whereas the more septic cases were progressive and showed finger-like extensions and often exposed underlying bone.

C diphtheriae was isolated in 7 out of 32 cases, but, as in many cases the ulcers had already been swabbed with formalin, it is believed that this was the main causal organism. Staphylococci, streptococci, *Proteus*, *P pyocyanea*, spore-bearers, and fusiform bacilli, the last-named in 4 of 60 cases, were also isolated.

An ulcer was produced in a guinea-pig by inoculating *C diphtheriae* into the flank with a small dose of antitoxin into the peritoneum at the same time, and in an Egyptian hedgehog (*Ermaceus auritus*) an ulcer was produced by inoculating material from a case showing fusiform bacilli, but attempts to produce ulcers in animals by inoculating other micro-organisms were unsuccessful.

The author believes that malnutrition is a predisposing factor. Most patients were on a poor diet deficient in protein, vitamin A, nicotinic acid, and riboflavin. The vitamin-A content of the blood was always very low. Serum calcium and blood urea were within normal limits, but the blood sugar was often low and curves flat.

Syphilis was a commonly associated infection and the Wassermann reaction was positive in 28.5 per cent of cases.

Nutritional defects were corrected and concomitant diseases treated, diphtheria antitoxin was given where indicated, and sulphanilamide powder was applied. Some dramatic results were obtained with the last named. The popular formalin-swab method was also used. The ulcers are cleaned up quickly by this method but their duration was not cut short, this is a very cheap form of treatment.

L E Napier

MISCELLANEOUS DISEASES

LAMPRELL, B A Tropical Neurasthenia *Med J Malaya* 1948, Sept, v 3, No 1, 34-40

The author during a long tropical service has seen a distressing number of cases of tropical neurasthenia including a number that ended in suicide.

The condition is common in Malaya of which he is writing. In a group of rubber plantations with an average staff of 75 (presumably Europeans) in the past two years one has committed suicide eight have been repatriated for nervous breakdown, and two have been sent on home leave for the same reason. In a series of 31 invalidings analysed by SQUIRES (no reference given) 45 per cent. [15] were for psychological reasons.

Neurasthenia in the tropics differs from that seen in practice in temperate countries by the predominance of cerebral over spinal symptoms. The mild cases show increased irritability with occasional outbursts of uncontrolled rages restlessness and moderate amnesia. In the intermediate cases these symptoms are worse and periods of worry and depression occur often amounting to delusions of persecution with insomnia. In the severe cases the depression is predominant to this is added procrastination and indecision, loss of confidence fear of insanity and of loss of employment which constitutes a vicious cycle that may end in suicide.

The author classes the causes as personal and environmental the former being the more important. The prominence of the personal factor is due to the tendency for social misfits and others who are dissatisfied with home conditions to seek employment in the tropics where they hope to find life easier. The environmental factors are (i) Exile from one's own country and loss of firm roots in a place that one calls home. (ii) The excessive stimuli of the tropics under this heading the author includes the direct effects of the climate and discusses the sexual factor. (iii) Overwork and excessive responsibility. (iv) Isolation and monotony. Under this last heading (the sequence of thought is obscure to the reviewer) he includes a suggestion that the recent increased rate of breakdown in Malaya may be due to years of war strain and present economic and political difficulties.

The preventive measures he advocates include more careful selection of candidates for service in the tropics and the suggestion that a psychiatric assessment as well as a physical examination should be made. More frequent home leave annual local leave to a hill station shorter office hours more security of tenure of appointments in commercial undertakings and freedom to marry early in his service. Finally the author suggests that since the problem is an admittedly serious one the Malayan branch of the British Medical Association should make a study of its aetiology and prevention and convey their conclusions to the Government and to commercial and industrial associations.

An account of 4 cases treated with either ephedrine or celvarian, with satisfactory results.

THÉODORIDÈS, J Les coléoptères parasites accidentels de l'homme [Accidental Infestation of Man by Beetles] *Ann Parasit Humaine et Comparée* 1948, v 23, Nos 5/6, 348-63 [39 refs]

Beetles or their larvae are sometimes recorded as having been taken from some part of the human body. Their presence is accidental as they are not parasitic on man. In a brief review of the published records the cases are grouped according to the site of infestation: (1) the digestive system, (2) the ear, nose and eye, and (3) the genito-urinary system.

A table is given summarizing the data concerning sixteen species.

REPORTS, SURVEYS AND MISCELLANEOUS PAPERS

CONGO BELGE Fonds Reine Elisabeth pour l'Assistance Médicale aux Indigènes du Congo Belge Rapport sur l'Activité durant les années 1946 et 1947 [DE BRAUWERE, P] [Report of the Activities of Foréami during 1946 and 1947] 140 pp, 3 maps & 3 diagrams [Recd 1949] Brussels 112 Rue du Commerce

The war-time experiences of the excellent Belgian organization Foréami were reviewed in the Report for the years 1939 to 1945 [this *Bulletin*, 1948, v 45, 816], which also sets out the general pattern of its organization. The present report covers the early stages of recovery and the preparation of plans for expansion. Work originally started in extremely unhealthy areas of the District of Kwango is now being stabilized in that district and in small areas of the Districts of Moyen-Congo and Lac Leopold II, divided into six sub-sectors with a total population of 624,600 people. The work includes the taking of an original census of the whole population, the medical examination of every person in his home, reinforced where necessary by laboratory procedures, and the preparation of a medical card for each. Each year the census is revised and as high a proportion as possible of the medical examinations repeated, 86 and 88 per cent having been re-examined in the years under review. In this way exceptionally valuable data are collected on the prevalence and social importance of different diseases, and on demographic happenings. In association with this survey the sick are treated either locally or by despatch to a hospital centre, public health education is carried out, and both general and special sanitary measures are instituted. The sick who report for treatment independently of their discovery in a survey process are also treated and constitute the bulk of patients.

The organization has now passed through its infancy. Much has been learnt by the survey process and public confidence has so increased that there is little remaining need to search for the sick. In the process of stabilization the survey will recede from its position of paramount importance to one of secondary importance in comparison with medical treatment and the improvement of health. The old dispensaries, once a local marvel, are now giving place to fully equipped hospitals in each sub-sector served by more elaborate rural dispensaries which have themselves some of the characters of hospitals, and staff are being transferred from survey to strictly clinical duties.

The commonest causes of morbidity and mortality are diseases of the respiratory and alimentary systems with nutritional conditions running them close. There was a remarkable absence of epidemic disease, the sole one worthy of notice being an outbreak of amoebic dysentery which proved unusually resistant to specific treatment [the statement that chiniofon "*semble être un*

mélancolie de premier ordre" in the treatment of this disease is not borne out by the data given. The state of the major endemic diseases is less satisfactory though trypanosomiasis (reviewed separately in this *Bulletin* 1949 Oct. v 46) has greatly decreased malaria remains a scourge demanding control by all possible means, while the helminthiases and nutritional deficiency diseases remain of the greatest importance. Yaws of which 75 new and 145 old cases were seen has sunk to a position of minor importance though previously extremely common and fortunately the incidence of tertiary cases reflect the present rather than the past incidence of primary cases. Leprosy remains common 0.4 per cent of the population being affected, and the standard methods of control by voluntary or compulsory isolation which have failed, are now being replaced by the establishment of a model village with a high standard of amenities to which patients will be attracted by treatment with the new drugs. Tuberculosis is a serious problem to combat which the five-year plan proposes to institute BCG vaccination mass miniature radiography and a model sanatorium. Venereal diseases are not very common. Helminthic infections are universal ankylostomiasis being the commonest, but the author makes refreshing comments on the excessive readiness of practitioners to attribute illness to this cause when others are responsible. Among all these various causes of sickness however the author focuses attention on the importance of malaria, which practitioners tend to regard as a mild disease but which he considers enhances the infant mortality in the absence of prophylactic treatment by about 150 per thousand. Against malaria Fortnam is instituting a control system based on house-spraying (the insecticide is not stated, but pyrethrum can be inferred) and on the wide use of prophylactic paludrine and chloroquine.

Demographic data are fully tabulated. During the war the birth rate dropped and though there was no marked increase in mortality other than the infantile mortality the population actually decreased in some areas. The position is now fully restored and the death rate is lower than any previously recorded. The following basic statistics for 1947 are either directly given or can be deduced from the tables—birth rate 41.24 per 1,000 crude death rate 23.75 natural increase 15.49 infant mortality rate 83.4 per 1,000 births fertility rate 176 and net female reproductive rate 1.3. The age distribution of the population and the mortality per 1,000 in each age group in 1947 were—

Age	Percentage of population in the group	Mortality per 1,000 per year
0-5	11.1	74.4
5-15 (inc. 14-14)	39.7	15.0
15-45 (15-44)	47.6	19
45 and over	6.6	67.0

The death rates by age groups are very high, roughly double those of India their nature being obscured in the crude death rate by the abnormally young age constitution of the population. Nevertheless the high fertility rate balances them and if this still continued, the population would be rapidly growing. (The reviewer is sceptical about the accuracy of the infant mortality rate which does not tally with the mortality in the 0-5 group but accepts the other figures as at least good approximations. The data given are unique for tropical Africa.)

The report concludes with notes on experimental work on paludrine and chloroquine prophylaxis and on the experimental human infection.

[For earlier accounts of the organization of Foream, see TROLLI, this *Bulletin*, 1940, v 37, 521, and HUMPHRIES, *ibid*, 523] G Macdonald

INDIA *Annual Report of the Malaria Institute of India for the Year 1947* [SINGH, J., Director] 19 pp 1948 Delhi Manager of Publications, Civil Lines

The Malaria Institute of India reports a successful year's work in 1947 despite the need for its staff to undertake much emergency work necessitated by refugee movements. Work must also have been impeded by several changes of staff exemplified by the fact that three Directors during the year are named.

Courses of instruction continued on a normal basis and a special one for engineers has now been standardized. Many papers have been published, and interesting points in the research programme dealt with laboratory trials of the prophylactic value of Cam-Aqi and resochin (chloroquin) against *Plasmodium knowlesi*, in which Cam-Aqi given in doses of 20 mgm daily for one week subsequent to inoculation proved effective in two monkeys. Field trials with paludrine showed it to be a highly effective therapeutic agent under Indian conditions, 0.1 to 0.3 gm effecting a clinical cure in most cases, and a prophylactic trial in which three dose regimens, approximating 300 mgm once a week, were employed was very successful. The notable feature of the work is the increasing amount of responsibility for routine malaria control in the Province of Delhi, in Coorg and in the coalfields. G Macdonald

HINMAN, E. H. *The National Malaria Society Past, Present, and Future.* J. *National Malaria Soc* 1949, Mar., v 8, No 1, 1-13, 1 fig

The National Malaria Society owes its origin to a resolution at the Pan-American Scientific Congress in 1916 which led to the formation of a Committee, whose objectives were (a) to stimulate interest in malaria problems, (b) to serve as a medium through which societies and individuals might become identified with the study and prevention of the disease, and (c) to co-ordinate the efforts of these agencies with constituted Federal, State, and local authorities. Until 1941 the Committee had an extremely varied career and was only successfully maintained through the activities of a few enthusiastic persons. In 1941, however, its constitution was radically changed and the National Malaria Society was formed in the place of the previous Committee, the Society undertaking the publication of the *Journal* which has now become well known.

With this change the Society has steadily prospered and undertaken much work in the co-ordination of malaria control activities both for the armed forces and the civilian authorities. In reviewing future prospects its officers foresee the possibility of its disintegration on the unique grounds that its objects may shortly be completely fulfilled by the disappearance of malaria from the United States. In this paper the writer reviews its place and considers the possibility of fusion with a society interested more generally in tropical medicine, following the example of the International Congresses. [Considering its recent successful career and the value of the *Journal* the arguments would seem to be strongly in favour of continued existence with interests extended from the United States to the tropical world.] G Macdonald

SHANGHAI *Rapport sur le fonctionnement technique de l'Institut Pasteur de Chang-Hai en 1948* [FOURNIER, J., Director] [*Annual Report of the Pasteur Institute, Shanghai, for the Year 1948*] 46 pp, 1 fig 1949

The first of the five parts into which this Report is divided deals with general laboratory investigations. Routine examinations are shown in detail in tabular

T. alani was not found in Malaya, Sumatra, Java, or the Philippines and so was regarded as not being a vector of the tropical variety of the disease [But Col. Ando to whom we are indebted for the copy of the report states that *T. alani* is common in Selangor where it as well as *T. deliusi* is definitely a local vector—he also states that the Japanese had many more cases of scrub typhus than are mentioned in the report—for example several thousand cases in Upper Burma whereas the only important outbreaks listed by the author are as follows—Kabanjar, Sumatra (80 cases in April, 1943), North Irrawaddy River bank (several hundred cases in October 1943), Atjeh, Sumatra and Phuket, Siam (more than 100 in each, in December 1944).]

At first the disease was not recognised, it was called Tensa (bushy wamp) fever. In October 1943 a rickettsia was first isolated from a patient by H. Tazui who described the disease as an unknown fever but the strain when examined by the author at Singapore in February 1944 was found to be *R. orientalis*. Even then the Japanese doctors who had seen tsutsugumushi disease in Japan believed that they were dealing with a different disease—they regarded the presence of an initial ulcer as an essential feature of the Japanese disease.

The author has carried out a remarkable thorough investigation which does him credit even though the chief importance of the experience of the Japanese medical men in connexion with scrub typhus is to serve as a striking example of the misconceptions that result from failure to recognise the wide range of variability of the disease.

[No 9

SUMMARY OF RECENT ABSTRACTS*

VII HELMINTHIASIS

[Continued from p 695]

NEMATODES

Hookworm infection, Strongyloides, Trichostrongylus, etc

ORLANDI (p 530) shows that in the rural population of Milan hookworm infection is fairly common (7 per cent of a large number examined) and *Ascaris* and *Trichuris* infections even more so. Women are more commonly engaged than men in market gardening, and work barefoot, they show higher rates than men. He describes the symptoms of the infection.

JENKINS (p 199) found hookworm infection in over 80 per cent of Papuans at Port Moresby, by direct and flotation methods.

In recent years there has been a great reduction in hookworm incidence in Florida, but HOOD (p 262) still finds that 40 per cent of white children are infected, though the infection is heavy in only 3.9 per cent. There is a sharp improvement in the rate at about the age of 20. The danger that service men who served abroad during the war may introduce hookworm infection into the United States is discussed by LOUGHLIN and STOLL (p 722). They estimate that *Ancylostoma duodenale* was acquired by 2-30 per cent of men, according to the theatre of war in which they served, but they also note that infection by *Necator americanus* was present in 18 per cent of men recruited from some southern United States. This reflects poor hygienic conditions, in which it may be possible that *Ancylostoma* may be established.

BENAIM PINTO (p 99) estimates that more than half of the people of Venezuela harbour hookworms. He describes cardiovascular disturbances in a group of patients with severe hookworm anaemia, some of the patients had other diseases, but some were regarded as having uncomplicated hookworm anaemia, and the cardiovascular disturbances were attributed to this cause.

KHOO and CHIANG (p 625) refer to previous descriptions of radiological changes in the small intestine due to hookworm infection, and describe the appearances in three of their own cases. Details should be sought in the original abstract.

BECMEUR (p 450) succeeded in eliminating hookworm infection from a group of miners in Morocco by treating all the moderately and heavily infected men.

*The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin*, 1948, v 45. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.

with tetrachlorethylene and by constructing effective trench latrines below ground so sited that no worker had to go more than 400 metres to use one. HERNÁNDEZ LIRA (p. 262) uses oil of chenopodium, hexylresorcinol and tetrachlorethylene in the treatment of hookworm infection. He gives details of dosage. In the Philippines it has been customary to give castor oil at the same time as oil of chenopodium but some prejudice has arisen because toxic symptoms were sometimes produced. GUTSARA (p. 277) notes that there were other ingredients in the mixture and he therefore tested the matter in cats and found that castor oil actually reduced the toxicity of chenopodium and he therefore advises that they should be taken together.

Benzene is used in veterinary medicine in Anatolia but is not pure. HAYAL (p. 802) has used a pure form in various worm infections of man with some success. There are slight symptoms of intoxication and burning sensation unless the dose is small.

It is noted that in the Philippines monkeys are the usual hosts of *Strongyloides* (p. 801) argues that geographical races of *Strongyloides* exist which vary in their capacity to infect dogs and cats. He cites instances to support his opinion.

LIE HIAN JOE (p. 99) reports *Tr. strongyloides* and *T. stercoraria* in considerable proportion of post mortem examinations in Indonesians and Chinese in Java. *T. stercoraria* was much more common than *T. strongyloides*. They did not give rise to symptoms in man but there was transient eosinophilia. O'NEAL and MAGATH (p. 802) report 3 cases of *T. strongyloides* infection of man.

LISSOS and B. REOLA (p. 1100) describe a case of infection with *Symptomatic* *Strongyloides* a rare parasite of man.

Ascari Trichuris et.

In the Cape Verde Islands hookworm infection is very common and *Ascaris* and *Trichuris* are also often found. A parasite is present in small numbers of people (Dr. MIRA *et al.* p. 1067). FLOCH and Dr. LAJONIE (p. 627) have made a survey of intestinal parasites in French Guiana. Comparing their results with those of an earlier survey they think that the incidence of parasites has fallen especially of *Ascaris* and *Trichuris*. Hookworm infection is common.

TUPAS and MAGALAC MONALES (p. 627) report several cases of intestinal obstruction due to infection with *Ascaris*. BRENNER with his colleagues (p. 1100) found *Ascaris lumbricoides* in the ileopancreatic patient. DAVIES *et al.* (p. 457) have demonstrated the antigenic properties of *Ascaris lumbricoides* by repeated injections of a crude extract of that worm.

LAZAROVA and B. STARR (p. 451) have used hexylresorcinol in a rural campaign against helminthiasis, particularly hookworm and *Trichuris*. Dr. MURDO *et al.* (p. 431) have used hexylresorcinol in the treatment of infection with considerable success but they note that in few cases were the cystoids were crushed they produced first-degree burns to the intestinal mucosa. LAR *et al.* (p. 351) used decoction of seaweed *Enteromorpha* in the Philippines when the infestation was severe.

For details the original should be consulted.

From Panama BROSIUS *et al* (p 1023) report a case in which ova of *Capillaria hepatica* were found in the faeces

TOUMANOFF and LE-VAN-PHUNG (p 354) report a case of infection with *Gnathostoma spinigerum* acquired either in Indo-China or Thailand They describe the symptoms Another case from Indo-China is described by TOUMANOFF and NGUYEN VAN HUONG (p 355)

Filarial infections

PINTO and DE ALMEIDA (p 1101) found microfilariae of *Wuchereria bancrofti* in about one-half of the people examined in Portuguese Guinea *Anopheles gambiae* appeared to be the chief vector *Acanthocheilonema perstans* was found in 3 per cent of those examined DILLER (p 101) found *W bancrofti* in Liberia, where there is evidence that *Anopheles gambiae* is the vector *Acanthocheilonema perstans* was found there also

GALLIARD (p 264) has observed complete development of *W bancrofti* in *Aedes aegypti*, and of *W malayi* in *Aedes aegypti* and *Aedes albopictus*, early larval stages of *W bancrofti* were found in *Aedes albopictus* MARKS (p 370) notes that *Aedes kochi* is an efficient vector of *W bancrofti* in Queensland, but that there is confusion as to its recognition She has published descriptions of this and related species

MURRAY (p 807) in American Samoa found microfilariae in the blood in about 5 per cent of children and 50 per cent of old people Elephantiasis was not observed below the age of 30 In those with elephantiasis (about 4 per cent of people over 30) there was a rather higher rate of microfilariae in the blood than in the non-elephantoid population FRANKS *et al* (p 453) report on *W bancrofti* infection in Okinawa, where (they think) all persons except very young infants are infected They used an antigen prepared from microfilariae of *Dirofilaria immitis*, for skin tests, and found that it had a limited value It does not give many false positive results, but it is often negative in persons with circulating microfilariae, or with elephantiasis

CHEN (p 1022) reports on filariasis in Fukien Province, China, where microfilarial incidence varies from nil to 30 per cent Microfilariae of *W malayi* were found in one-fifth to one-third of the positive cases HU (p 1022) has found that *Culex pipiens* var *fallens* is a poor vector of *W malayi*

Survey work carried out by BUTTS (p 352) indicates that Limon on the Atlantic coast is the original endemic area of *W bancrofti* infection in Costa Rica, *Culex quinquefasciatus* [*fatigans*] is the probable vector GIGLIOLI (p 628) has shown that *Anopheles darlingi* is a good vector of *W bancrofti* in British Guiana

Clayton LANE (p 802), before he died, set down in detail his argument on filarial periodicity His theory was that female *W bancrofti* each day give birth to large numbers of embryos, which appear in the night blood, and that each day these embryos are destroyed by the reticulo-endothelial cells of the host He supported his argument by reference to a large number of slides of histological material left by the late Professor O'Connor The argument is complicated and the reasoning is close, and the original, or the original abstract, should be consulted GALLIARD *et al* (p 1101) observed the effect of extirpation of adult *W bancrofti* on the rhythm of periodicity and persistence of microfilariae General anaesthesia has no effect, and destruction of a considerable number of adult female filariae has little effect on the number of microfilariae On the other hand, surgical shock and physiological disturbance are capable of exciting immediate and prolonged dislocation of microfilarial rhythm

WARTMAN (p 1020) has contributed a most important paper on the early manifestations of filariasis seen in men of the United States Services who

served in Samoa and other islands. The usual incubation period was 5-12 months, but adult worms have been found within 3 months of first exposure. The most common signs were lesions of the genitalia and lymphadenitis of inguinal, femoral, axillary and epitrochlear glands. Microfilariae were not often found in the blood, but they or adult worms, were found in 22 per cent. of biopsies. Bacterial cultures of biopsy material were almost always negative. A description of pathological findings is given. Hypersensitivity is probably the explanation of many common symptoms. Intradermal tests were positive in over 80 per cent.

HARTZ and VAN DE STADT (p. 352) describe a case of microfilarial granuloma of the female breast.

ZELIGS (p. 189) shows that the intradermal test for filariasis in which a saline extract of *Dirofilaria immitis* was used as antigen, could not be relied upon for the diagnosis of *W. bancrofti* infections, since it was negative in 25 per cent. of suspected cases and positive in 19 per cent. of controls. From experiments on skin tests for filariasis in rabbits WILKINSON *et al.* (p. 808) conclude that cross reactions with intestinal helminths do not ordinarily occur.

OTTO *et al.* (p. 353) who studied blood levels and excretion rates of persons with *W. bancrofti* infections who were given trivalent or pentavalent antimonials by injection, found that the former compounds had much greater affinity than the latter for red cells. The pentavalent compounds were excreted in larger amounts than the trivalent immediately after injection probably because they are not bound to the red cells. Excretion is more rapid at the end than at the beginning of treatment and the plasma concentrations are maintained for only a short time. It is wise therefore to give injections at as short intervals as are compatible with safety. Intervals of 1" or 24 hours are suggested.

CULBERTSON (p. 101) reports work done by himself and his colleagues on the chemotherapy of filariasis. They showed that in *Latomosoides corrusi* infection of the cotton rat, pentavalent antimonials kill the adult worms quite quickly but that the microfilariae persist for months in the blood. In *W. bancrofti* infections of man, neosalvarsan was the most satisfactory of the antimonials but none of these drugs was ideal. In *L. loa* infections there was apparently some benefit but not with *O. cofnasus*. In discussion of this paper HAWKING made the point that the longevity of the microfilariae after treatment renders assessment of results difficult unless observation is prolonged. He had found arsenicals even more active than antimonials. ROBERTS (p. 214) recalls his early results in the treatment of filariasis with tartar emetic noting that in some cases the microfilarial counts fell steadily for 3 months after treatment. In these the adult worms had probably been killed. He refers to the work of Culbertson (above) who showed that microfilariae persist for long periods in the blood.

SANTIAGO-STEVENS *et al.* (p. 355) report that two days after administration of Hetrazan by mouth for 3-71 days, microfilariae of *W. bancrofti* were absent from, or greatly reduced in the night blood of a group of infected patients in Porto Rico. There was evidence which suggested that the drug had a lethal effect on the adult worms. [See HEWITT *et al.* below.]

The pharmacological properties of Hetrazan are described by HARNED *et al.* (p. 628). Its toxicity is low.

LOVETT-CAMPBELL (p. 723) discusses the surgical treatment of large elephantoid scrota. Details should be sought in the original. Surgical treatment of elephantiasis of the legs is dealt with by DR REYES PUGHURE (p. 922) who describes his operation in detail.

PERTRAM (p. 285) describes his experiments to determine the period required by *Latomosoides corrusi* to reach the infective stage in *Lepomis* *baoti* and

the length of time during which the mite is infective. Transmission is associated with feeding, but the exact mode is not known. Mites are infective within 15 days of the infecting blood meal, and some remain so until the 36th day after the infecting meal. SCOTT (p 808) has devised a method for infecting cotton rats with relatively constant numbers of *Litosomoides carini*. WHARTON (p 103) describes the pathological changes in *L. carini* infections of the cotton rat. The reactions seem to be due primarily to the excretions of the living worms, and not necessarily to disintegration of dead worms.

HEWITT *et al* (p 454) have tested a large number of organic non-metallic compounds in dogs infected with *D. immitis* or cotton rats infected with *Litosomoides carini*. They describe the techniques and the criteria of effectiveness adopted. The best balance between activity and toxicity was found in the piperazines, administered orally or intraperitoneally. The same group of workers (p 455 *bis*) report in detail on the piperazine compound 84-L (Hetrazan), which acts directly on microfilariae, producing a rapid and great reduction in their numbers, and also, but less certainly, on the adult worms. It may be given to animals by mouth or peritoneum, and in the doses used it did not display severe toxicity.

Onchocerciasis occurs in the Bahr-el-Ghazal Province of the Sudan, and KIRK (p 531) found positive skin smears in 19-90 per cent of people examined in various places, with nodules in up to 46 per cent and blindness in up to 10 per cent. Hydrocele and scrotal elephantiasis were very common, but infection with *W. bancrofti* was very rare. MAZZOTTI (p 922) notes that onchocerciasis is prevalent in Mexico, where the vectors are *Simulium ochraceum*, *S. callidum* and *S. metallicum*. He notes that allergic attacks may occur, with fever and local induration of the skin. In treatment he uses Hetrazan in doses of 2 mgm per kilo body weight, thrice daily for 3 weeks or more. MAZZOTTI and HEWITT (p 532) treated with Hetrazan a few patients suffering from onchocerciasis. There was apparently some reduction in microfilariae in the skin, but some nodules extirpated later still contained living adults and microfilariae. NOBLE (p 354) has examined the tissues of the eye in onchocerciasis, and concludes that microfilariae may be found in all the tissues, but have a predilection for the conjunctiva.

VAN HOOFF *et al* (p 456) report very favourably on Belganyl (Antrypol, Bayer 205) in the treatment of onchocerciasis. A dose of 1 gramme each week to a total of 7 grammes is usually enough for cure, a total of 10 grammes appeared always to be successful. RUIZ REYES (p 265), however, has tried Naphuride sodium (which is the same as Bayer 205) in onchocerciasis, but without recognizable benefit.

Various filarial infections (*W. bancrofti*, *O. volvulus*, *L. loa* and *A. perstans*) are present in SW Sudan. WOODMAN (p 627) thinks that although *L. loa* can develop in *Chrysops distinctipennis* and *C. longicornis*, the process is so slow, and the flies are so rarely attracted to man, that some other vector probably exists.

FAIN (p 100) has carried out a survey of human filariasis in the Banningville territory, Belgian Congo. A focus of *W. bancrofti* infection was found, and several foci of *O. volvulus*. More interest attaches to *Dipetalonema streptocerca* which predominates in the south, but is also found along the Wamba and Kwango rivers. The cause of its distribution is not understood, it does not produce clinical symptoms. *A. perstans* is found throughout, especially in riverside villages, *L. loa* is rare. PEEL and CHARDOME (p 809) have found *Dipetalonema streptocerca* (*Agamofilaria streptocerca*) in chimpanzees in the Belgian Congo, and describe the adult worms. They also describe the adult *O. rodhami* from chimpanzees.

DEJON (p. 1103) shows that cysts containing dead or disintegrated *Dracunculus* may resemble cold abscesses and may be found in patients who have never expelled a worm. He describes 3 cases, in 2 of which the cyst was on the forearm.

Enterobius Trichinella

GAYTON *et al* (p. 809) found *Enterobius* infection in 37.6 per cent. of 157 children examined in South Vancouver. All types of families were involved. More than one-third of a series of children examined in Honolulu were infested by *E. vermicularis* (ALICATA and KARTMAN, p. 833) and AMATEX (p. 829) found 47 children in São Paulo positive for the same worm.

DESCHIEUX and LAMY (p. 629) discuss the merits of the various drugs used for *Enterobius* infection. For healthy adult patients they prefer purified phenothiazine but for children and anaemic adults they prefer subnitrate of bismuth. They discuss the action of gentian violet and other dyes which are less toxic than phenothiazine. BLOOM *et al* (p. 201) have treated 123 children with phenothiazine in *Enterobius* infestation and report good results.

ERNARDY (p. 1023) discusses the drugs which have been used in the treatment of *Enterobius* infection. He concludes that none is reliable.

The incidence of *Trichinella spiralis* in diaphragms taken at autopsy in England was 10.8 per cent. (LOUNG, p. 355). There was evidence that infection had taken place both recently and a considerable time ago. The fact that cysts of obviously different ages were found in a single cadaver indicated that one infection did not confer immunity.

An outbreak of trichinosis in a camp of German prisoners of war in the United States was traced to canned bacon and pork, which had been eaten raw. DAVIS and CLELAND (p. 399) report that most of the patients suffered from mild diarrhoea and a condition rather like influenza but with more muscular pain. Eosinophilia was common and some patients had sub-conjunctival haemorrhage.

STARKER (p. 457) found adult *Trichinella* in male and female sections of the large and small intestine of a man who died 54 days after eating raw pork. Such a finding is rare. Larvae were extremely numerous in the diaphragm, and were also present in the heart (causing myocarditis) and testis. It is important to attempt to remove adults from the intestine but anthelmintics are of little use; the author advocates purgation and perhaps administration of convalescent serum.

In an outbreak of trichinosis at a military school in Chile VIGNER *et al* (p. 350) noted that though symptoms on the whole were typical but mild, some patients showed a rash which was at first thought to be that of typhus. SKINNER (p. 630) describes two patients with trichinosis in whom there were severe mental and neurological changes during the acute stage of the illness. Both patients recovered from the mental changes but left residual signs persisted (for instance unilateral tensor plantar rigidity).

OLIVER-GONZÁLEZ and HEWITT (p. 870) tried Hetrazan in experimental trichinosis giving the first dose 24 hours after infection. The results (on rats) indicated considerable effect in reducing adult worms and larvae in the treated animals, compared with controls. (For details see p. 870.)

coloured figs on 1 pl [13 refs] English summary (4 lines) in *Lavori
dell' Istituto d'Igiene d Univ di Cagliari 1940-1946* 1949

A comprehensive summary of the work on exoerythrocytic schizogony is given, beginning with the speculations of GOLGI in 1893, continuing with the work on avian forms and ending in 1945 on the debatable ground of so-called E E forms in human malaria

The authors investigated 85 cases of human malaria in Cagliari by the examination of sternal puncture material There were 53 cases of *P falciparum* malaria (22 primary cases and 31 relapses), 31 of *P vivax* (10 primary and 21 relapses) and 1 relapsing case of *P malariae* So-called E E forms were observed in 6 of the *P falciparum* and 5 of the *P vivax* cases, both in primary attacks and in relapses, and in febrile and afebrile cases A coloured plate illustrates the findings The *falciparum* forms are extracellular bodies, round or oval, slightly larger than an erythrocyte and contain up to 8 masses of chromatin, but no pigment The cytoplasm is strongly basophilic The *vivax* forms are of similar type but much smaller, with a maximum of 5 masses of chromatin The authors obviously studied their results critically, they examined the bone marrow of 25 patients with no malaria, with negative findings, and concluded that these bodies were not broken-off fragments of cytoplasm of marrow cells but, on the contrary, might be referred to the exo-erythrocytic stage of malaria parasites

[This is one of the papers which ANGELINI (this *Bulletin*, 1948, v 45, 24) criticizes on the grounds of insufficient morphological evidence]

MUDROW-REICHENOW, Lilly Unser heutiges Wissen von der Plasmodien-
entwicklung im Wirbeltier [Our Present Knowledge regarding the Develop-
ment of *Plasmodium* in the Vertebrate] *Ztschr f Tropenmed u Parasit*
Stuttgart [1949], v 1, No 1, 113-52, 2 figs [Numerous refs]

Since the discovery of the exoerythrocytic development of *Plasmodium* there have appeared numerous reviews of the contemporary state of our knowledge of the life-cycles of the malaria parasites in the vertebrate host The present paper is one of the most recent and extensive reviews of this subject It includes works published in Germany during the war years and subsequently chiefly by the author herself, by Kikuth and by Reichenow, working singly and in collaboration

These observers have made a number of important contributions to our knowledge of the exoerythrocytic development of the avian malaria parasites, for

which they have not always received the credit they deserve. It is difficult to review adequately a paper which is itself a review. Those interested in the subject should consult the original. The following will give some idea of the questions dealt with and of the author's own views.

The first section of the paper is devoted to the exoerythrocytic (EE) forms of the avian and reptilian parasites. A general account is given of their development in various species of *Plasmodium*. It is noted that the special positive of *P. douglasii* which develops in cells of the haemopoietic system is more apparent than real for it would seem that in infections following the inoculation of sporozoites this parasite behaves like the other avian species, in that it develops in reticulo-endothelial cells. The initial stages of development of the sporozoite were described independently by RICHMOND & MURKOW (1943, [this Bulletin 1944 v 41 180]) in *P. relictum* and by HOFF and COETSKOV (1944) (*ibid.* 1945 v 42, 538) in *P. gallinaceum*. The German and American authors also showed that there were two types of exoerythrocytic schizogony: one giving rise to macromeronts which continued the EE cycle, the other giving rise to macromeronts which invaded the erythrocytes where they continued to multiply asexually or became gametocytes. In this respect the avian species of *Plasmodium* differ from the human ones and show a closer similarity to *Haemoproteus*. EE development in the chronic phase of the infection occurs in *P. gallinaceum* and *P. cathemerium* but has not been demonstrated for *P. relictum*.

The author next discusses the relation of EE stages to the blood forms and notes that while sporozoites introduced into the host invariably develop in reticulo-endothelial cells, the inoculation of blood forms gives rise both to EE forms and to erythrocytic stages. The latter are therefore capable of reverting to the former. As regards the bearing of EE development to immunity, some observers have shown that immunity acquired in the course of an infection protects against superinfection and reinfection with both EE and blood forms, while others found that it did not protect against infection with sporozoites of the same strain of parasite. The author believes that in the latter case development does not proceed beyond the earliest EE stages.

The author then turns to the host-cells of avian EE forms which are primarily phagocytic cells situated in different organs and tissues. Cultures of EE forms in bird embryos and tissues are then dealt with. The culturability of these forms in chicken-tissue apparently depends on the viability of the host's macrophages; therefore it is to be expected that those species of *Plasmodium* which invade these cells will readily grow in tissue-cultures.

The second section of this paper is devoted to the Haemosporidia of mammals. Attention is drawn to the special position of the parasites of bat and of *Hepatoscys* of monkeys in which only gametocytes are found in the blood. The bat parasites seem to have affinities with *H. emmonsi*, while *H. jayakari* is more closely related to *Leucocytozoon*. A detailed account is given of the discovery of the EE development in *P. cynomolgi*. The author credits mainly to the previous discovery by GARNHAM of the asexual stages of *Hepatoscys* which in the liver of infected monkeys thus *Haemosporidia* (1947 v 44 187, 1948 v 45 683). The author supports the view that there is only one pre-erythrocytic generation in *P. cynomolgi* and that it is not able to infect other monkeys with liver material during the incubation period.

Finally an account is given of the development of our knowledge regarding the EE stages in human malaria parasites. Their existence was first inferred from circumstantial evidence, this led to prolonged searches by numerous investigators culminating in the discovery of EE stages of *P. falciparum* in human liver by SHOOTER, GARNHAM & VILL & WHITE in 1948 v 45 487.

Although the existence in human malaria parasites of an EE development has now been established beyond doubt, a number of questions are still unsolved. Thus nothing is yet known regarding the tissue stages of the other three species of *Plasmodium*, the earliest stages of development of the sporozoites in man have not been demonstrated, it has not been definitely settled whether there are one or more pre-erythrocytic generations, and whether merozoites differing in size are produced. The author and REICHENOW (1949) suggested that since the rapid disappearance of the sporozoites from the circulation is presumably due to phagocytosis by endothelial cells, their initial development, before they invade the parenchymatous cells, probably takes place in the reticulo-endothelial elements of the liver.

In conclusion, it is stated that the new findings throw light on the affinities between various species of *Plasmodium* and on their relationship to *Haemoproteus* and *Leucocytozoon*, which proved to be much closer than was previously suspected. However, a revision of the systematics of the Haemosporidia should not be attempted until the life-cycles of more species of *Plasmodium* from vertebrates are thoroughly studied.

There is an extensive bibliography of works published since 1941 the earlier literature is listed in a previous paper (KIKUTH & MUDROW *Erg Hyg*, 1941, v 24, 1) [For a full review of the EE schizogony, see also GARNHAM, this *Bulletin*, 1948, v 45, 831] C A Hoare

BOVENTER, K Ueber das Verhalten der Malaria-parasiten im konservierten Blut [The Behaviour of Malaria Parasites in Preserved Blood] *Ztschr f Tropenmed u Parasit* Stuttgart [1949], v 1, No 1, 91-101 [24 refs]

After noting what others have recorded on the persistence of malaria parasites in blood withdrawn from the body and kept for various lengths of time, the author records his own investigations. The blood was drawn into a solution containing sodium citrate 5 gm, dextrose 40 gm, in a litre of distilled water, the proportion of preservative being 3 : 1 or 10 : 1, it was kept in paraffin-capped tubes in quantities of 8-10 cc, or in larger ampoules holding 250 cc. The subjects were nine patients who had been infected by mosquitoes, 5 with subtertian and 4 benign tertian infections. The blood was kept at 37°C, at 21° and at 4° and was examined at intervals up to 150 days. The morphological changes in the parasites from time to time are noted, their loss of definition, loosening of pigment which may be seen lying free in the corpuscles, change of shape to the semicircular or coronoid form, fragmentation of the chromatin, disappearance of the plasma, etc. These changes take place rapidly, within a day at 37°C, more slowly at 21° and still slower at 4°. The subtertian parasites lived longer than the benign, and even after 100 days the differentiated "resistance" forms of *P. falciparum* were recognizable, and some even at 150 days.

The infectivity was tested by inoculating amounts varying from 6 cc to as much as 90 cc (the former intramuscularly, the latter intravenously), using blood kept from 6 to 150 days. Thirty-two inoculations were made, 18 with *P. vivax*, 14 with *P. falciparum* blood. Five infections resulted, 3 with *P. falciparum*, 2 with *P. vivax*. The longest times of preservation to yield a positive result were 13 days with *P. vivax* and 21 days with *P. falciparum*, 10 cc of the former had been injected and 85 of the latter, both intravenously. ROSE and WOLPERT's record of infection with blood preserved for 90 days the author could not confirm. BREINDL, V & KOCHÁREK J. *Anopheles* Czech & Moravia [*Anopheles* of Bohemia and Moravia.] *Časopis C. Zoologické Společnosti v Praze* Prague 1940 v 8 17-85 1 text fig & 5 pls. Summary in Latin.

The following is a translation of the authors' summary —

- 1 Two species of *Anopheles* namely *A. clariger* and *A. maculipennis* are found in Bohemia and Moravia.
- 2 Only two varieties of *A. maculipennis* are found namely *A. maculipennis typicus* and *A. maculipennis messiae*.
- 3 The anophelines are not found free in nature but almost entirely in stables and human dwellings.
- 4 *A. m. messiae* is met with most frequently especially in the neighborhood of fish ponds and the banks of streams.
- 5 *A. m. typicus* is much less frequent and occurs only in the lower hilly country.
- 6 *A. clariger* (*infurcatus*) is found throughout but principally in hilly regions where aestivo-autumnal malaria might be found.
- 7 Among the three species there are neither purely zoophilic nor purely anthropophilic forms.
- 8 *A. m. atroparvus* has not been encountered so far in Bohemia and Moravia.

CEPULCHI P & MINO, A. L. *A. (Anopheles) hyrcanus* var. *pseudofictus* in provincia di Venezia. [*Anopheles* (*M. zerkynus*) *hyrcanus* var. *pseudofictus* in the Province of Venice.] *Riv. di Malariologia* 1949 Apr v 28 No. 1 125-7 2 figs.

The English summary appended to the paper is as follows —

"The presence of *Anopheles* (*Macrosynthesus*) *hyrcanus* var. *pseudofictus* in the territory of Venice is signalled for the first time. A review is made of the Anophelines represented in the same territory.

McINTOSH, J. A New Variety of *A. phlebotomus* from Burma. *Bull. Entom. Res.* 1949 May 40 Pt. 1 49-52, 2 figs.

RACHON R, G. FREIRE, M. O & FERREIRA D. M. D. distribuição vertical das criadouras dos mosquitos do sub-genero *Anopheles* em condições permanentes. The Vertical Distribution of Breeding Places of Anophelines of the Subgenus *Anopheles* under Experimental Conditions. *Rev. de Med. Mal. trop.* Rio de Janeiro, 1949 Jan. v 1 No. 1 31-8 3 figs.

From data collected from the examination of thousands of bromeliads the authors have previously shown that it is the lower plants (less than 100 cm) which are the most important breeding places of the larvae of *Anopheles* in the tropics.

In this paper they describe how it was determined that the vertical distribution of the breeding places of these anophelines is not the same in all the regions. They give the results of the examination of the bromeliads in the different regions and show that the vertical distribution of the breeding places is not the same in all the regions.

OVERMAN, R R, HILL, T S & WONG, Y T Physiological Studies in the Human Malarial Host I Blood, Plasma, "Extracellular" Fluid Volumes and Ionic Balance in Therapeutic *P vivax* and *P falciparum* Infections *J National Malaria Soc* 1949, Mar, v 8, No 1, 14-31, 13 figs [30 refs]

Physiological and biochemical estimations were made in 70 patients suffering from syphilis of the central nervous system, 42 of them were suffering from induced *vivax* and 28 from *falciparum* infections. The infections were about equally mosquito- and blood-induced. More than half those examined were negroes.

Measurements were made of blood plasma and "extracellular" fluid, erythrocyte volumes, whole blood, plasma, erythrocyte and urine concentrations of sodium, potassium and chloride, urinary volumes and urinary excretion of potassium, sodium and chloride, plasma total protein, haematocrit, changes in body weight, temperature, parasitaemia, etc. The methods used are briefly described, sodium and potassium were measured by the flame photometer, plasma volume by the use of the dye T-1824, a multiple sampling technique being used, extracellular fluid volume by the thiocyanate method.

Control figures were obtained before the induction of malaria. After the controls had been obtained the patients were infected. From then on serial determinations were made during the active clinical stage of the malaria, and in convalescence after antimalarial treatment. The results obtained qualitatively corresponded with those observed by the authors in *P knowlesi* infections in monkeys. The changes observed are considered in the text against "the number of days of positive parasitaemia". According to the authors, they might equally have been measured against the number of paroxysms or the number of hours of fever. In the general discussion of results, those obtained in *vivax* and *falciparum* infections are grouped together since there were no qualitative and few quantitative differences observed in these infections. Controls were considered to be syphilitic patients who had not yet been infected with malaria.

The authors found that parasitaemia rises almost linearly up to the last observation before antimalarial treatment, the linear rise representing the number of hours of fever and the number of paroxysms continued beyond the period of introduction of treatment. There is some confusion here as the figures for each point on the text curves are obtained by taking the average values of "20-50 cases" including in some instances cases in which antimalarial treatment had been begun. The authors' arguments are thus sometimes difficult to follow.

Changes observed in blood volume were equivocal. There was progressive reduction in red-cell volume which became more pronounced after the sixth day of the malaria, and which was usually offset by a roughly equivalent increase in plasma volume. There were, however, cases in which there was a profound reduction in volume. These were suddenly fulminating cases few of which responded to treatment. A diagram illustrating the changes in three of these cases is given.

Extra-cellular volume increased progressively during the disease, as in *P knowlesi* infection [see this *Bulletin*, 1948, v 45, 766]. In some cases there was evidence that the cyanate must have entered the tissue cells, because the figure obtained approximated to that of the total body water. This indicated that there was some alteration of permeability of cell membranes, which normally exclude the cyanate.

The authors examined the balance between the tissue fluid and sodium, potassium and chloride of the cells. These ions in whole blood reflected

progress and anaemia. As the haematocrit value fell the sodium rose and potassium decreased. The ionic content of plasma was examined before, during and after paroxysms in rarer infections and the rise of potassium and fall of sodium content during the paroxysm, frequently described by other authors, was confirmed. There was not always any striking *proportional* change in the concentrations of these ions during the disease.

There was however a general linear reduction of the average potassium content and an increase in the sodium content of the non-parasitised erythrocytes. This was not statistically significant probably because the malaria was controlled. It was significant in infections in monkeys which were allowed to run a fatal course. In some of the human cases the changes in sodium and potassium content of the cells were pronounced. A brief account of such cases is given. The authors suggest that there is probably an exchange of sodium for potassium in the uninvaded erythrocytes.

These changes in ionic balance recover apparently only slowly during convalescence. The authors found recovery in some cases took weeks or months and refer to such slow recovery as "cellular convalescence".

There was a reduction in sodium chloride output in the urine which was more obvious in fatal malaria in monkeys. In the human cases, unlike monkeys, the potassium output also fell. The authors suggest that possibly in more severe malaria the reverse would have occurred.

Only total plasma proteins were estimated and these in terms of total protein per kilogramme of body weight. There was no constant loss of body weight and therefore the rise in total circulating protein reflected the increase in plasma volume. The authors suggest that both water and protein must be added to the blood in malaria and the reduction observed in total protein can be explained on the grounds of addition of relatively more water than protein.

On the whole they agree with ELLMAN and MURPHY (J. Clin. Invest. 1945, 24, 780) that anaemia in malaria is due not only to blood destruction but also to dilution of the blood possibly as an intermittent process coincident with the paroxysms.

(This paper is an interesting attempt to cover some of the more obvious gaps in our knowledge of the physiological processes underlying malaria. It contains much useful information but it is pity that more details of individual cases have not been given. The authors have grouped their results together in batches of unknown numbers again according to the period under figure 1 from 20 to 50. The various stages of the malaria have not been sufficiently clearly separated off. For instance in one set of figures the final point seems to include a mixture of both treated and untreated cases. No doubt the authors adopted this method of expression for their results for simplicity's sake but in a disease like malaria which varies so much from person to person this is unfortunate. The studies over the period of convalescence are not included in this paper, they are promised in future papers. The reviewer looks forward to further work of this kind.)

RILEY, J. A. & ROBINSON, C. M. Leukemoid Reaction due to Mixed Malaria Infection. Report of a Case. *Blood* 1947, Vol. 4, No. 3, 263-7 figs.

There are in the literature references to the presence of immature forms of the granulocyte series during malarial paroxysms but there is no previous reference given to a definite leukemoid reaction in malaria. See this Bulletin 1928, 24, 141.

The case presented was that of a negro resident in the Philippines about a month after leaving that country for a limited hospital in the U.S.A.

with a sharp febrile attack clinically diagnosed as malaria. The diagnosis was not, however, confirmed for about a month and he was not given specific treatment until parasites of *Plasmodium vivax* and *Plasmodium falciparum* had been found in the peripheral blood (A figure shows *P falciparum* gametocytes and *P vivax* trophozoites only)

On admission, his blood picture was 1.16 million red cells per cmm, 4.0 grammes haemoglobin per 100 cc, and 4,000 leucocytes per cmm (band forms 14 per cent, metamyelocytes 21 per cent and myelocytes 11 per cent). With blood transfusions, the red cell count improved and subsequently, even during the severe febrile attacks of untreated malaria during the next month, there was no return of metamyelocytes or myelocytes to the blood, but band forms varied up to 30 per cent.

On the 6th day after admission, when the temperature was almost normal, a sternal marrow smear showed a marked increase in the early forms of the neutrophil series but few "blast" forms—a tentative diagnosis of myeloid leukaemia was, however, made on the smear. When the malaria parasites were eventually found in the blood, the patient was given a full course of atabrin [mepacrine] and apparently cured. A second sternal marrow smear 12 weeks after the first showed a normal picture.

BLACKBURN, C. R. B. Observations on the Development of Resistance to *Vivax* Malaria. *Trans Roy Soc Trop Med & Hyg* 1948, Sept, v 42, No 2, 117-62, 15 charts [23 refs]

This is a report of work carried out in the Medical Research Unit, Cairns, during and immediately after the war. It deals with the development of tolerance and immunity in healthy volunteers who were experimentally infected with *P vivax*, and who had not previously been exposed to malaria.

In his introduction the author points out that resistance to *vivax* malaria may be manifested in one or both of two ways—

"1 There may be less reaction by the host to a given bulk of infection—tolerance

"2 There may be an increased ability of the host to limit the bulk of infection developed—immunity"

The paper is divided into three parts. Part one deals with experiments designed to illustrate the development of tolerance and immunity after mosquito-transmitted malaria. Part two deals with experiments designed to show that the development of tolerance precedes that of immunity, and that immunity is strain-specific. Part three refers to experiments illustrating the development of tolerance after the use of various chemotherapeutic agents.

The paper is very long and detailed, and it would be impossible to deal with it fully in a short review. The interested reader is referred to the original. The author's conclusions may be given in full.

"1 Tolerance to the effects of *vivax* malaria developed before an enhanced ability to deal with the invading parasite

"2 Tolerance and immunity developed in response to *P vivax* trophozoite activity rather than to activity of exo-erythrocytic forms, the degree of tolerance and immunity depended on the bulk of the trophozoite experience of the individual.

"3 Volunteers who had become tolerant to one strain of *P vivax* showed definite tolerance to trophozoites of another strain of *P vivax* on their first experience of the second strain. Tolerance to *P vivax* is not necessarily strain-specific

"4 Subjects who had become immune to one strain of *P vivax* did not exhibit any enhancement of their anti-parasitic mechanism when infected

with trophozoites of another strain. Anti-parasitic immunity may be strain-specific.

"5. Subject who had developed complete tolerance and solid immunity to their trophozoites were perfectly fit, had impalpable spleens and had normal or super normal haemo-globin concentrations though trophozoites could be found in their circulating blood whenever adequate examinations were made. Attempts to induce malaria attacks by severe chilling and alcoholic excess were unsuccessful.

"6. Gametocytes were never seen in the peripheral blood of subjects who had developed complete tolerance and immunity to their infection. No tumors were not infected by the blood of these immune subjects.

[Some of the diagrams are difficult to follow. They have been repeated in a smaller form that it is often impossible to read the details. There is some slight confusion in the text with regard to charts 14 and 15.]

B. G. MATTHEW

BOYD M. F. & COLLIER H. D. A Note on the Apparent Antagonism of a Bacterial Intoxication to a Plasmodial Infection. *Amer J Trop Med*, 1949 Mar. v. 29 No. 2, 193-202.

A male negro with a diagnosis of meningo-encephalitis syphilis was inoculated by mosquito with *P. falciparum* (Costa strain) on 25th June 1946. Parasites were first observed on 6th July and on the following day the temperature first exceeded 100° Fahrenheit. Remittent fever continued until the 11th during this period the parasite count slowly increased to reach 7,870 per cmm. on the 11th, which the authors consider a low density for infection with this parasite. A single dose of quinine three grains was given on the 9th. The temperature rose to 100°F on the 14th and quinine three grains was repeated. From then on the parasite density rapidly declined to 10 per cmm. on the 18th. The temperature however persisted and ten grains of quinine were given on the 18th and two more doses of ten grains were given on the 19th. The blood smear on the following day was negative and parasites were never subsequently observed. On the 19th a crepant cellulitis in the perineal region was discovered. The patient was treated with penicillin and tetanus gas gangrene antitoxin and the necrotic tissues were drained. *Clostridium welchii* was grown from the exudate of the lesions. The patient eventually recovered and was watched until 31st July 1947.

The authors point out that the malaria infection in this case was typical because the parasites did not attain a density proportionate to the level of temperatures experienced. The plasmodial therapy administered would not have been sufficient to abort the malaria infection had they been that the *C. welchii* infection which was probably of known origin. The discovery may lead to a soluble extract which would kill the malaria parasites.

F. C. MATTHEW

KREYER R. L. in collaboration with J. A. WILSON & C. L. HARRIS. Chloroquine Manufacture. A Staff Industry Collaborative Report. *J. S. I. & E. in Chem*, 1949 Apr. 41 No. 4 654-6. 5 Lys. 22 ref.

When America entered the recent war she possessed small stocks of quinine and atabrine mepacrine. The need for supplies of these materials was keen and the search for new compounds was co-ordinated by the Office of Scientific Research and Development whose organization has been described by WYSTOLES in "A Survey of Antimalarial Drugs 1941-45" (this Bulletin 1947 v. 44 1107). During the period 1941-45 least 14 C₁₀ and C₁₂ alkaloids were

synthetic chemicals and natural products, were screened. One substance submitted for test by the Winthrop Chemical Company was 3-methyl-4-(4-diethylamino-1-methylbutylamino)-7-chloroquinoline (German Sontochin). Tablets found on German prisoners in Tunisia were identified in America as the same substance, which was now designated SN-6911. Work on this group of substances was intensified in the U.S.A. and a related substance, minus the methyl group in position 3 in the quinoline nucleus, was named chloroquine, now Aralen (German Resochin) and was assigned the number SN-7618. Both Sontochin and Resochin had already been synthesized and tested for antimalarial properties in Germany before the War. The former was considered the more active by the Germans but the Americans found otherwise. A number of reports on the properties of chloroquine (Aralen) have been given by the latter authors [this *Bulletin*, 1946, v 43, 708, 1948, v 45, 955, 960]. When it became necessary to produce the drug on a large scale, indications of a method of synthesis were available in the U.S. patent literature but details were absent. American chemists evolved new methods of synthesis and one of them is fully described in the present article, along with details of production costs. In this particular plant, the manufacture of 5,000 lb of Aralen diphosphate per month was attained and improvements are constantly being introduced.

J D Fulton

VAN DER WALLE, N. Behandeling van malaria aan de kust van Peru met araken [The Treatment of Malaria with Aralen (Chloroquine) on the Peruvian Coast] *Nederl Tijdschr v Geneesk* 1949, May 21, v 93 (ii), No 21, 1698-703

After describing the American work on chloroquine, a detailed description is given of an investigation by Torres Portugal in two Peruvian sugar plantations. On each plantation about 400 persons were selected and the blood examined for parasites. In one case 20.5 per cent of those examined were infected, in the other 30.5 per cent. There were 128 cases, of which 80 had benign tertian, 39 subtertian and 7 quartan malaria. Two patients had a combined infection (*P. vivax*+*P. falciparum*).

Of these, 37 patients were treated with another preparation, SN 8173.5 (7-Cl-4 [3-diethylamine-2-hydroxypropylamine] quinalnebisphosphate), this was found to have unpleasant side-effects and was abandoned. The others were treated with chloroquine, adults having 4 tablets of 250 mgm chloroquine, children of 1-12, 0.5 gm and children under one year 0.25 gm. All were treated as out-patients and seen daily. The blood was examined every day until it was negative. If parasites were still numerous the day after treatment was begun a further dose of 500 or 250 mgm was given and this was repeated if necessary on the third day. After this every patient had a single weekly suppressive dose of 250 mgm.

Young forms of all three types of plasmodia had always disappeared in 24 hours, adult schizonts in 48 hours and the gametocytes of *P. vivax* and *P. malariae* within 72 hours. The sexual forms of *P. falciparum* did not disappear for 6-10 days.

There was no doubt as to the beneficial effect on clinical symptoms. In every case the temperature was normal in 24 hours and after 48 hours the patients felt well. In 14 cases (mainly women) there were toxic manifestations including abdominal pain, headache, lassitude, dimness of vision, vomiting, giddiness and sleeplessness. None caused any anxiety.

In six cases of benign tertian malaria, suppressive therapy was deliberately omitted after parasites had disappeared from the blood. Relapses occurred after 31-51 days.

JELLINEK D. B. Proguanil Prophylaxis and Intercurrent Infection. *Lancet.* 1949 June 18 1052-3

Previous correspondents in Nigeria referred to a case where 0.1 gm. of proguanil daily failed to prevent a break through of *falciparum* malaria [see DAVEY & SMITH this *Bulletin* 1949 v 46, 706]. The present author also in Nigeria, discusses the prophylactic dosage of proguanil and quotes three cases in Europeans to show that 100 mgm. daily may be insufficient in the presence of intercurrent infection.

The first patient, who had been taking this dose daily in the Sudan for four months developed subtertian malaria with a positive blood film, during an attack of multiple boils. The second, also in the Sudan, had been taking the same daily dose for two months. She developed proved amoebic dysentery which cleared up with emetine treatment but at the end of th treatment she developed an attack of *P. falciparum* malaria. The third patient in Nigeria, had been taking 100 mgm. proguanil for 5 months. He had lamitude joint pains and occasional rises of temperature. Physical signs and blood films were negative but the dose of proguanil was increased to 200 mgm. t.d.s. Five days later bile pigment was found in the urine and a few days afterward he developed hepatitis. This was probably a virus hepatitis, as his wife had had a similar non icteric illness three weeks before. He improved rapidly on appropriate dietetic treatment. About two weeks later he suddenly developed a temperature of 101 F and a heavy blood infection with *P. falciparum* rings.

All these bouts of malaria were mild and short-lived and responded rapidly to therapeutic courses of proguanil usually 200 mgm. t.d.s. for 10 days.

There seems to be no doubt that all the patients had been taking their proguanil without missing a single day.

The author suggests that until the metabolism of proguanil is better known the prophylactic dosage should be increased if the patient has an intercurrent disease however slight. He recommends that at least 200 mgm. should be given daily for malaria prophylaxis both during and in the convalescence following any intercurrent infection.

BEATRÁN E. & VIERO C. V. X. Ensayo del valor de la palodrina en el tratamiento supresivo del paludismo en Boca del Río, Ver. [The Value of Palodrine in suppressing Malaria in Boca del Río, Vera, Mexico.] *Rev Inst. Salubridad y Enfermedades Trop.* Mexico. 1949 June v 9 No. 2, 123-32. English summary

This study of the suppressive action of palodrine against Mexican strains of malaria was carried out on 140 conscripts in a Naval Battalion in Boca del Río, where malaria is endemic. The men were all 18 years of age. They were divided into four groups each of 35 men. Men of Group A were given 0.10 gm.

paludrine once a week, of Group B, 0.30 gm paludrine once a week, of Group C, 0.10 gm paludrine twice a week. Group D were controls receiving no paludrine. The experiment lasted 30 weeks from October to May, 1948. The men were kept under medical observation and blood smears were examined weekly.

There was no clinical malaria among the men receiving paludrine. *P. falciparum* was found in the blood of one man in Group A during each of the first four weeks of observation but not afterwards. Another man of Group A had a single positive *P. vivax* smear in the tenth week.

One man of Group B exhibited *P. falciparum* parasites from the fourth to the eighth week.

No positive blood smears were obtained from Group C.

Parasites were found in 8 men of the control group in which there were 6 cases of clinical malaria, one *P. falciparum* and 5 *P. vivax*.

During the spring recrudescence of malaria no man receiving paludrine had a parasitaemia.

Two weekly doses, each of 0.10 gm, gave the best results. *Norman White*

SHELLEY, H. & AZIZ, M. Anopheles Eradication in Cyprus. *Brit Med J* 1949, Apr 30, 767-8

A brief history of malaria in Cyprus is given. *Plasmodium falciparum*, *P. vivax* and *P. malariae* infections have been recorded from the island. The vectors against which the present eradication scheme was directed were *Anopheles superpictus*, *A. elutus* [sacharovii] and *A. bifurcatus* [claviger].

An anti-larval campaign was begun in April, 1946, and anti-adult measures against hibernating adult anopheline mosquitoes were instituted from the winter of 1946-7 onwards, effective eradication of these vector species from the island has apparently been obtained. No anopheline adults nor larvae have been found in the thirteen weeks preceding the preparation of the present report. It is thought that, apart from maintenance measures, the campaign can be terminated during the summer of 1949.

In 1944 7,686 cases of malaria were reported in Cyprus but this figure had dropped to 406 in 1948 and of these only three were considered to be of recent origin. In school children splenomegaly and parasitaemia dropped from 32.4 per cent and 51.9 per cent respectively in 1944 to 10.6 per cent and 1.3 per cent respectively in 1948. In 1948, 655 infants (under 2 years of age) in formerly highly malarious villages were found to be negative for parasites.

Occasionally "Malarial", Paris Green, and fuel oil were used in the anti-larval work, but the greater part of the larval control was achieved by the use of 3-4 per cent DDT in gas oil. Winter control of adult mosquitoes was effected by "light treatment with DDT" of resting places. Later, in 1948-9, DDT and "Gammexane" smokes were employed against adults in buildings with high ceilings and for other inaccessible places. Considerable efforts were made to trace and to treat adult resting places in caves, tombs, tree trunks, etc., and to deal with all breeding or resting places besides those in or adjacent to centres of habitation. Indeed, every effort was made to destroy the adults and the larvae of anophelines in every part of the island. A brief account of the organization involved is given. The island was divided into six districts and these were subdivided into 39 sections, 111 zones and 556 blocks. A block comprised an area which could be covered by one man in a period of twelve working days.

Observations on the effectiveness of the control measures were made not only by the staff responsible for the work but also by independent observers.

The estimated cost for the campaign was given as £310,000. [See also this *Bulletin*, 1949, v 46, 16.]

FIELD J. W. & EDISON J. F. R. A Note on Presumed *Exo-Erythrocytic* Development of *Plasmodium russali* in the Liver of the Malayan Squirrel. *Trans. Roy. Soc. Trop. Med. & Hyg.* 1949 May v. 42, No. 6 543-72. 8 figs. on pl.

A pigmented parasite of the red blood cells of Malayan squirrels was studied. The organism was thought to be probably the same as that described by various authors as *Plasmodium russali* from squirrels in Indo-China, India and Malaya. Seventy-nine squirrels belonging to four species of *Callosciurus* and one species of *Lariscus* were examined and 68 were found to harbour the infection, some very heavily. Gametocytes only were observed in the blood stream. The surface of the liver in many of the infected animals was studded with cysts; smears from which showed innumerable merozoites. Schizogony was not observed in the brain, lung, spleen, bone-marrow and kidney, nor in the peripheral blood. The liver cysts measured up to 840 μ in diameter and closely resembled the merocytes of *Hepatozoon leuck* (this Bulletin 1948 v. 45 680) a parasite of African monkeys. The cyst was a smooth, round, translucent body with an outer wall of compressed liver parenchyma, sometimes containing giant and other inflammatory cells and surrounding a rim, 50 μ wide, tightly packed with merozoites. The interior of the cyst contained amorphous material. Smears made from a cyst showed an immense number of merozoite-like structures, mostly single but sometimes multiple together with extracellular dividing forms with two to six or more segments of chromatin.

[The authors conclude the paper by asking various questions regarding the systematic position of this parasite of the squirrel. Although its early asexual stages remain undescribed, it would appear to the reviewer justifiable to call it *Hepatozoon russali* and to regard the cyst-like liver structures as the mature asexual forms of the parasite.]

PARAENSE, W. L. The Latency in *Lophura* Malaria of the Chicken. *Worm. J. d'Osvaldo Cruz.* 1949, Mar v. 48 No. 1 81-7. 7 graphs. [Portuguese version 73-81.]

P. lophurae malaria is primarily a disease of the fire-back pheasant. In the duck it causes a virulent infection; in the domestic fowl the disease is usually said to run a mild and self-sterilizing course. The Rockefeller strain was maintained in Brazil by intravenous inoculations of infective blood into chicks 5-20 days old. The infection reached a peak of parasitaemia about 3 per cent by the eighth day and subsequently declined rapidly. Subinoculations of 0.25-0.5 cc. of blood were performed up to 330 days after inoculation and all the birds developed low-grade infections. Quinine treatment of the initial attack scarcely affected the eventual survival of parasites; 4 out of 5 birds passing into the latent stage which lasted for at least as long as 136 days after the original quinine treatment.

The well-known phenomenon of increase in virulence after repeated transfers was again observed in *P. l.* larvae in chicks; the parasitaemia eventually reached over 10 per cent, and proving fatal.

McGEE, R. B. The Course of Infection of *Plasmodium gallinaceum* in Duck Embryos. *J. Infect. Dis.* 1949 Jan-Feb 84 No. 1 104-104. 2 figs. [10 refs.]

Adult ducks are only lightly susceptible to infection with *Plasmodium gallinaceum*. Tests were made to observe the behaviour of the parasite in duck embryos. Blood containing a known number of parasites was inoculated intravenously into duck embryos of various ages. All attempts to transmit

a blood infection by inoculation into the chorio-allantois were unsuccessful) The younger the embryo, the more severe was the resultant infection, though all became infected in the end 14-day-old embryos were all killed by the disease, 20-day-old embryos nearly all died, at 26 days, all the infections progressed to a crisis, with development of acquired immunity and recovery, while 2-day-old ducklings responded with only transient low-grade infections Sporozoite infections were initiated by the intravenous inoculation of infected salivary glands from *Aedes aegypti*, ground in a mixture of chicken serum and saline Such infections were studied in 14- and 20-day-old duck embryos They were all accompanied by a heavy tissue parasitism (in liver, spleen, heart and brain) which killed the embryos uniformly, in the blood, in addition to the ordinary pigmented schizonts, unpigmented forms were found free or in basophil erythroblasts, polychromatophil erythroblasts, lymphocytes and neutrophils The author points out that there is a series of adaptations of the parasite, after its liberation from the fixed tissue elements—it first shows a preference for cells of the lower erythrocytic series and for lymphocytes, and later a major alteration in its physiology allows it to develop in the mature erythrocytes where it forms pigment and becomes more susceptible to the immune processes of the host

McGHEE, R B Pre-Erythrocytic Development of *Plasmodium gallinaceum* in Avian Embryos *J Infect Dis* 1949, Jan-Feb, v 84, No 1, 105-10, 12 figs on pl [10 refs]

Pre-erythrocytic forms of *Plasmodium gallinaceum* are readily obtained by the inoculation of sporozoites into chick embryos 12 to 16 days old Infected salivary glands of *Aedes aegypti* were implanted on the chorio-allantoic membrane (usually at a vein bifurcation) intramuscularly in wing or leg buds, or elsewhere in the body, and intravenously after grinding The course of development followed closely that described by HUFF and COULSTON [this *Bulletin*, 1945, v 42, 538] in wing skin Only a few sporozoites managed to survive to start the cycle, there was a rapid dispersal from the reaction area, and normal development took place in the macrophages By 24 hours, the chromatin of the cryptozoite divided into two masses and a well-defined vacuole surrounded the parasite as it lay in the cytoplasm of the host cell By 36 hours there were 30 "nuclear structures", at 40 hours, all nuclear differentiation was lost and clefts appeared, followed by separation into oval merozoites with pointed ends arranged radially around a central core The metacryptozoic generation matured about 70 hours after inoculation and resembled the corresponding stages of cryptozoite development Similar stages were seen in the vascular endothelium of the organs the clefts in the cytoplasm of mature schizonts were more noticeable and gave the appearance of cytomere formation In these organs, even as long as 9 days after infection, synchronicity of development was well marked, and this finding was the main point of difference between infections in embryos and in the wing skin of adults where lack of periodicity is apparent even after 70 hours Macro- and micro-merozoites were produced by exo-erythrocytic segmenters in the spleen

NADFI E M TAYLOR D Jane GREENBERG, J & JOSEPHSON, E S Adrenal Hypertrophy in Chicks Infected with *Plasmodium gallinaceum* *J National Malaria Soc* 1949, Mar v 8 No 1, 70-79, 5 figs [24 refs]

Changes in the adrenal glands during the course of *Plasmodium gallinaceum* infections in chicks were observed Week-old chicks were inoculated intravenously with blood containing 1,000 parasitized erythrocytes, and the

following observations were made—weight of birds, red blood counts, degree of parasitaemia and the weight of the adrenals taken from chicks at different stages of the infection. Similar observations were carried out on an adequate number of control birds kept under identical conditions. The glands were removed first by a block dissection of an area about 2 cm. square and subsequently under a low power lens the ovoid orange adrenals were isolated from the ovaries, connective tissue etc. A dissection could be completed in 15 minutes.

The results were assessed in relation to body weight and were compared with a similar relationship in normal birds. In the latter the weight of the adrenals is directly proportional to the body weight. Up to a parasitaemia of about 80 per cent., there is scarcely any hypertrophy of the adrenals but beyond that density the glands show a marked increase of weight—on an average they are twice as heavy at the peak of parasitaemia and in one chick, were five times as heavy. With the decline in the blood infection, the glands revert to normal size. The increase in weight was shown to be due not merely to fluid but to an increase in tissue elements. Hypertrophy of the adrenals is known to be caused by starvation but this was proved not to be the explanation of the results in the case of chicken malaria. There are coincidental maxima of anaemia and of adrenal hypertrophy—the authors refrain from ascribing this to cause and effect.

[The authors state that material was taken for histological study, but the results are not recorded in this paper. They might well throw light on the possible aetiological association between malaria and Addison's disease which has been reported on a number of occasions after severe infections with *P. falciparum* in man.]

BLACKWATER FEVER

RIGDON R. H. Hemoglobinuria (Blackwater Fever) in Monkeys. A Consideration of the Disease in Man. *Amer. J. Path.* 1949 Mar & 23 No. 2, 195-209 7 figs. on 2 pls. [36 refs.]

This report is concerned with the clinical and renal pathological findings in 10 rhesus monkeys (out of 27 infected) which developed haemoglobinuria after intraperitoneal, subcutaneous and intravenous injection of parasitized blood (*P. knowlesi*).

In the kidneys of monkeys in which haemoglobinuria continued to the time of death there were few changes in the glomeruli, but the epithelial cells of the convoluted tubules were always damaged. These cells were sometimes swollen to the point of occluding the lumen, sometimes fragmented or desquamated into the lumen. Small masses of yellowish-brown pigment (occasionally staining faintly with Prussian blue) were present in the cytoplasm and similar masses appeared in the lumina of the tubules. The epithelium of Henle's loop was desquamated, especially in the region of large casts. Casts were present in varying numbers. They were sometimes large homogeneous and pink staining, and sometimes composed of groups of deep eosin-staining granules, approximately equal in size to a red blood corpuscle, sometimes considerably smaller. Other tubules contained amorphous yellowish-brown material. Casts were present in large numbers in the collecting tubules and sometimes in the convoluted tubules. There was no significant change in the interstitial tissue. The small blood vessels were filled with parasitized cells but there

were no specific vascular lesions. In one monkey, which was killed shortly after recovery from haemoglobinuria, the kidneys were normal in size and colour, and no casts were present.

According to the author, younger monkeys with severe infections were especially prone to develop haemoglobinuria, the appearance of which was influenced by the severity of the infection. The CO_2 -combining power was estimated in one animal. It was low, suggesting a severe terminal "acidosis". The presence or absence of either oliguria or anuria was not determined in these experiments, but the author discusses the incidence of these phenomena in monkeys and in blackwater fever in man. He considers that the amount of material within the lumina of the tubules is insufficient "to produce anuria in the manner suggested for cases of the so-called 'lower nephron nephrosis'". Anoxia and shock are probably more important factors. He points out that in severe malaria symptoms of shock may occur and that glomerular filtration, since it is influenced by blood pressure, is probably significantly decreased in the presence of shock. He suggests that such a mechanism is "more significant in producing anuria in blackwater fever than obstruction in the lumina of the tubules".

[The author was one of the earliest to stress the importance of anoxia in the pathogenesis of malarial lesions. His views on the production of anuria are in line with those recently expressed in a considerable volume of literature which is not discussed in this paper. Interested readers are referred to the original.]

B G Macgrath

TRYPANOSOMIASIS

HORNBY, H. E. Electrical Charge of Trypanosomes [Correspondence]
Trans Roy Soc Trop Med & Hyg 1949, May, v 42, No 6, 626-8

This paper deals with experiments designed to test the validity of a method for determining the electric charge of trypanosomes, described by FAIRBAIRN and CULWICK [this *Bulletin*, 1947, v 44, 649]. According to these observers, this can be done in a thin stained blood film, by noting the position of the trypanosomes in relation to the erythrocytes: those in contact with the cells are said to be positively charged, while those not touching the red cells are negatively charged. It is also claimed that the results obtained by this method and by the salt-concentration test [this *Bulletin*, 1937, v 34, 511] are in close agreement.

The author doubts this contention on purely *a priori* grounds. "In view of the very short time required for the making of a thin film, and the relatively terrific mechanical forces to which the blood ingredients are submitted when the blood is spread, it would appear strange that trypanosomes—which are not adherent to red cells in the circulating blood—should within a second or two of release from the circulation, and while submitted to violent mechanical disturbance be able to orientate themselves in any way that is not dictated by this disturbance."

The author then describes experiments, in which he and other observers at Mpapwa carried out parallel tests by both methods with a Tinde strain of *Trypanosoma rhodesiense* maintained in guinea-pigs, which at different periods showed a great predominance (80 to 100 per cent) of trypanosomes carrying a charge of the same sign. Whereas there was complete agreement between these observers regarding the charge on the trypanosomes examined by the

saline-glucose method, their results were completely at variance when the thin film method was used. Thus, in one experiment two observers agreed that 97 per cent. of the trypanosomes tested by the former method were negative's charged, but when they examined the position of the trypanosomes in stained films, one of them reported 93 per cent. and the other 29 per cent. of the trypanosomes as bearing a negative charge.

The author concludes "that the positions of trypanosomes in thin films are governed entirely by the action of the glass spreader—the closer together the elements of the blood, the more likely are the trypanosomes to touch cells; the more widely the red cells are scattered, the more likely is a trypanosome to be detached from all other cellular elements."

[The reviewer is informed of a similar experiment carried out in Britain, in which the observer failed to confirm the results obtained by the glucose-saline test, when he attempted to determine the charge of trypanosomes of the corresponding strains in blood films.]

C. A. HARRIS

FAIRBAIRN H & CULWICK, A. T. The Differentiation of the Polymorphic Trypanosomes. *Ann Trop Med & Parasit* 1949 Apr v 43 No. 1 90-95. [15 refs.]

The authors have made a biometrical study of the polymorphic trypanosomes with the view to detecting morphological differences which would serve as a basis for the differential diagnosis of *Trypanosoma gambiense*, *T. rhodesiense* and *T. brucei*. For this purpose they employed 5 strains of *T. rhodesiense*, 4 of *T. brucei* and one of *T. gambiense*. All the strains, except one were transmitted by *Glossina* and the metacyclic forms were recovered from these flies by induced salivation. Measurements of length were made of both the blood and metacyclic forms of the trypanosomes, in preparations stained by Giemsa's method. The blood forms were obtained from dog, monkey, gazelle and from rats and guinea-pigs inoculated from these hosts and from man and sheep. The results of measurements of several hundred flagellates in each of the normal strains are given in two tables, which can be summarized as follows (Table A) —

TABLE A.

Mean Lengths (i μ) of Polymorphic Trypanosomes (Figure 1 shows represent the mean of means)

	<i>T. rhodesiense</i>	<i>T. gambiense</i>	<i>T. brucei</i>
Blood form			
Short	18.35-19.90 19.25	19.28-21.99 20.30	18.51-21.39 19.31
Intermediate	22.81-1.5 3.51	22.83-1.58 23.49	22.06-1.57 23.71
Long	28.56-30.23 29.43	28.07-30.62 29.06	28.25-30.68 29.1
Metacyclic forms	16.38-18.11 17.24	14.17-15.97 15.24	16.1-18.31 17.42

Among the trypanosomes used in this study there were also two strains of *T. brucei* No. 8 and No. 9 which behaved very differently from the other strains of this species. The measurements of the typical strains on different dates were as follows (Table B) —

TABLE B
Mean Lengths (in μ) of atypical *T. brucei*

	Strain 8	Strain 9
<i>Blood forms</i>		
Short	16 48, 17 18	18 23, 16 81, 14 96
Intermediate	21 12, 23 48	22 77, 23 73, 21 25
Long	28 77, 29 42	26 53, 29 02, 26 00
<i>Metacyclic forms</i>	15 21-16 56 15 68	14 99-16 21 15 69

In discussing the results the authors point out that the polymorphic trypanosomes examined by them fall into two groups. In one (shown here in Table A) represented by 5 strains of *T. rhodesiense*, 2 of *T. brucei* and one of *T. gambiense*, the length frequencies of the various forms tend to normality, while the mean lengths are similar and fluctuate only within small limits. However, the mean length of the metacyclic forms of *T. gambiense* is significantly shorter than that of the other two species, and can serve to differentiate it from the latter.

In the second group (shown here in Table B) are strains 8 and 9 of *T. brucei*, in which the mean length of the blood forms "fluctuates widely, and the length-frequency distribution curves are often abnormal, suggesting a mixture of two or more components." The mean lengths of the metacyclic forms in these strains are also significantly shorter than those of the strains of *T. brucei* adduced in Table A. Further investigations indicated that measurements comparable to those in *T. brucei* strains 8 and 9 were obtained in a mixed experimental infection of rat with *T. rhodesiense* and a "normal" *T. brucei*. The significance of this finding will be discussed by the authors in a future publication.

The authors record other interesting observations on *T. brucei* carried out in the course of this work. In the case of three strains, which were recovered from dog, wild tsetse fly and camel, respectively, the identification of the species was checked by inoculation of human volunteers. The canine strain was tested very thoroughly by allowing heavily infected *Glossina morsitans* to bite 10 men, some of them repeatedly. When none of the men became infected they were inoculated subcutaneously from infected rats, each man receiving from 600 thousand to 42 million trypanosomes. Again not a single infection resulted. The other two strains likewise failed to produce an infection in man. [The first of these tests is perhaps one of the most thorough experimental attempts to infect man with *T. brucei*.]

C. A. Hoare

SPINKS, A. Fluorimetric Determination of "Antrycide" [Correspondence] *Nature* 1949, June 18, 954

A preliminary note

PELLERGRINO, J. O perigo da transmissão da doença de Chagas pela transfusão de sangue. Primeiras comprovações sorológicas de esquizotripanose em doadores e em candidatos a doadores de sangue. [The Danger of transmitting Chagas's Disease by Blood Transfusion. Evidence of the Disease in Blood Donors.] *Brasil-Médico* 1949, Feb 19 & 26, v 63, Nos 8/9, 63

The English summary appended to the paper is as follows —

"It is surprising that the danger of inoculating Chagas' disease through blood-transfusion has not yet been duly considered, and that apparently

nothing is being done in order to prevent it. This danger is a real and serious one for the following reasons. Chagas disease and its natural vectors are widely spread in this continent and in large rural areas this infection is exceedingly frequent. Most doctors are not aware of it. Infection lasts for many years apparently is not susceptible of spontaneous cure and there is no effective treatment for it. While many cases may stay symptomless for a long time a large proportion of infected people show severe heart trouble. *Schizotrypanum cruzi* is easily transmitted through the inoculation of blood into susceptible hosts.

"The writer reports for the first time the occurrence of Chagas disease among people serving as blood-donors in Belo Horizonte Brazil. Three individuals were found which exhibited a strongly positive complement fixation test (*S. cruzi* culture antigen). Formerly they used to live in mud huts with triatomid bugs in the interior of Minas Gerais. Two showed no signs or symptoms of Chagas disease but one showed heart trouble (right bundle-branch block).

"The writer emphasizes the necessity of preventing the dangerous possibility of the spreading of Chagas disease through blood transfusion. It suggests that the complement fixation reaction for *S. cruzi* be necessarily performed in all individuals before they are admitted as blood-donors, in the countries where the disease is known to occur. People exhibiting positive or even doubtful tests should be obviously discarded.

PELLOUX A. & DECOURT P. Toxicité du S.P.N. ou sulphos (thiophosphate o diéthyl o parantrophényl) sur des triatomides vecteurs de la maladie de Chagas. [Toxicity of Thiophosphate o diethyl o parantrophényl (Sulphos) on Triatoma Vectors of Chagas's Disease.] *Bull Soc Path Exot* 1949 v 42 No. 1/2, 22-5.

The authors describe experiments in which S.P.N. was used as a powder and as an emulsion against *Triatoma infestans*. S.P.N. is thiophosphate o diethyl o parantrophényl and is also known as Sulphos.

(1) Groups of five insects were confined in Petri dishes which had been dusted with S.P.N. at concentrations from 1 part S.P.N. in 200 parts of talcum powder to 1 part in 1,000. The powder was distributed evenly giving a deposit of 0.5 mgm. per sq. cm. 100 per cent. mortality was obtained after 48 hours at a concentration of 1 part in 1,000.

(7) Specimens of *T. infestans* were placed in wire mesh cages with wooden floors which had been sprayed with emulsions of S.P.N. in water at concentrations from 1 part in 10,000 to 1 part in 20,000 giving a deposit 1.00 cc. per sq. cm. At a concentration 1 part in 2,000 the symptoms were immediately obvious but the insects remained immobile for several days before death occurred.

The elimination of *T. infestans* from houses has been on a large scale in Brazil. The authors advise the use of 0.25 per cent S.P.N. in powder for use in habitations, and show that at this concentration the risk of toxicity to man is exceedingly small.

[It is added in a footnote that in the United States a product having the same chemical formula as Sulphos is called Thiophos but the authors suggest that the higher toxicity of the latter according to published data seems to indicate that the two products are not absolutely identical.]

WILDER, J. H. H. Experimental Use of Dimidium Bromide (15-3) in the Treatment of *T. cruzi* Infection in Zebu Cattle. *J. Comp. Path. & Therap.* 1949 Jan v 59 No. 1 45-53.

LEISHMANIASIS

KIRK, R. Studies in Leishmaniasis in the Anglo-Egyptian Sudan. X. An Interesting Strain of *Leishmania*. *Trans Roy Soc Trop Med & Hyg* 1949 Mar, v 42, No 5, 501-2

In a previous paper (this Bulletin, 1945, v 42, 875) the author described a case of leishmaniasis in a monkey (*Cercopithecus aethiops*) infected intraperitoneally with the Sudanese kala azar which had previously been passaged from man through two other monkeys. The monkey showed symptoms of visceral leishmaniasis combined with cutaneous and mucocutaneous lesions. In order to follow this curious condition further, four monkeys of the same species were inoculated with material from the first monkey as follows: two intraperitoneally with splenic pulp and two subcutaneously with material from the nasal lesion. All the material contained numerous leishmanias. Observations in the course of four years after inoculation of the infected material revealed no symptoms of disease in any of the four monkeys and on post mortem examination there was no evidence of a leishmanial infection. The author concludes that the strain of leishmania lost its virulence for monkeys in the course of passages through these animals when it went through a stage producing metastatic cutaneous and mucocutaneous lesions. GOPPA, D. M. & CHATTERJEE, J. R. Kala Azar with Purpura, a Case Report. *Calcutta Med J* 1949 Jan, v 46 No 1, 24-6

HO, I. A., SEONG, Tsung-hen & LI, Y. Rate of Disappearance of *Leishmania* in Kala-Azar Patients under Urea Silbamline Therapy. *Trans Roy Soc*

than of those having twice-weekly injections were negative for example in group (2) after 2, 4 and 6 injections of urea silbamine the percentages showing negative sternal punctures were 78.6 94.6 and 99.4 among those having the injections weekly and 41.7 77.7 and 98.3 among those having them twice weekly. The blood picture also improved after a smaller number of injections when the injections were given at weekly intervals.

In a follow-up of patients over a period of three years (one year after the last patient was treated) 4.1 per cent. of the patients on twice-weekly injections and 1.3 per cent. on weekly injections relapsed. Another group of 528 patients who returned for examination were in normal health. 353 had negative sternal punctures and 45 negative spleen punctures.

DE ARRUDA, W. DA COSTA, F. C. NUNES, S. & ROSENFIELD, G. Leishmaniose visceral americana. Constatação de dois casos. [Two New Cases of American Visceral Leishmaniasis.] *Brasil-Médico* 1949 Feb. 19 & 20 v. 63 Nos. 8 & 9 64-5 1 map.

The English summary appended to the paper is as follows —

Two new cases of American visceral leishmaniasis are presented. They were diagnosed by the finding of leishmanias in spleen material.

"With all the probability one of these patients had the disease in the Brazil-Bolivia Railway area, Bolivia, and the other is original from a new focus of the disease in Matto Grosso.

LEPROUX, G. La leishmaniose cutanée au Soudan français. Fréquence de la forme sèche papulo-tuberculeuse [Cutaneous Leishmaniasis in the French Sudan. Prominence of the Dry Form.] *Bull. Soc. Path. Exot.* 1948, v. 41 Nos. 9 & 10 622-7

Oriental sore was first reported from French West Africa in 1911 in the Niger Colony; later more cases were reported from there and from Chad, but none from the French Sudan to the West. This was surprising in view of the similarity of the nature of the country. However in 1944 reports were received from a young doctor Dr Verges, who had been familiar with the disease in Zinder, that the condition was relatively common in Timbuktu. Later a case of the dry papular form in an official from Legon and another case of the ulcerating form were diagnosed by Dr Kervran at Bamako. As a result of these observations a circular on the diagnosis of this disease was sent to all doctors in the French Sudan and, in 1945, 138 cases were reported and the diagnosis confirmed at Bamako. Cases undoubtedly also occur beyond the administrative frontiers of the Sudan.

The commonest was the classical ulcerative form which could be confused with craw-craw or ecthymatous ulceration or when it occurs in the legs, phagedenic ulcer.

The form that calls for special mention is the dry form in which the lesion gives the name papulo-tubercular. The lesions are large round red raised papules covered by a scab which rapidly re-forms if scratched off. They show no tendency to ulceration and usually heal in a few months time leaving a distinct scar.

Four species of *Phlebotomus* *P. perniciosus* var. *papalis* *P. macleayi* *P. dydi* and *P. fuscus* have been found. Samples of the *P. papalis* group are widely scattered in the Sudan, but are difficult to catch. It is apparently the only sandfly that is pathogenic to man. *Phlebotomus* *Phlebotomus* and its distribution coincides with that of cutaneous leishmaniasis.

Tartar emetic was used in the treatment of cutaneous leishmaniasis with satisfactory results. The dry form has been treated by dermal infiltration of

quinacrine [mepacrine] thrice weekly, with mediocre results. the ulcerative form was treated with many different antiseptics and caustics also

FEVERS OF THE TYPHUS GROUP

Fox, J P The Relative Infectibility of Laboratory Animals and Chick Embryos with Rickettsiae of Murine or of Epidemic Typhus *Amer J Hyg* 1949, May, v 49, No 3, 313-20, 1 fig [14 refs]

The author has investigated the possibility of obtaining animals more suitable than guinea-pigs for the isolation of typhus rickettsiae. The results obtained and the technical methods employed will be of great interest to workers on the typhus fevers.

The most important findings obtained when freshly isolated strains of rickettsiae were used are as follows —(1) The cotton rat was slightly more susceptible than the guinea-pig to murine and epidemic strains of rickettsiae. (2) The mouse was as susceptible as the cotton rat to murine strains, but relatively insusceptible to epidemic strains. (3) The chick embryo was as susceptible as the cotton rat to murine strains, but usually less so to epidemic strains, though after repeated egg passages epidemic strains became equally infectious for rats and embryos. (4) The cotton rat was considered to be the animal of choice for the isolation of both epidemic and murine infection from material obtained in the field, though the mouse is equally suitable for murine strains. (5) Rickettsiae persisted for long periods in the brain and kidney of cotton rats infected with epidemic and murine typhus, yolk-sac cultures being obtainable from suspensions of these organs up to 60 days. This persistence suggests that the existence of infection in the rats may be capable of detection by serological examination before attempts are made to isolate rickettsiae.

The establishment of recently isolated strains by yolk-sac cultures was often difficult, bacteriological contamination caused failure in 52 out of 245 passage series, and in most cases two or even three successive passages were needed before positive results were obtained.

John W D McGaw

Snyder, J C, Murray, E S, Yeomans, A, Zarafonitis, C J D & Wheeler, C M The Effect of Typhus Vaccine on the Numbers of Rickettsiae in Body Lice of Typhus Patients *Amer J Hyg* 1949, May, v 49, No 3, 340-45, 1 fig [14 refs]

The material employed in this important study consisted of pooled suspensions each made from 200 lice which had been allowed to feed for ten days on a typhus patient in a Cairo hospital. The suspensions had been rapidly frozen and stored in sealed glass ampoules which were kept in an alcohol-dry-ice cabinet till they reached the laboratory in the U.S.A. where they were rapidly thawed and diluted with sterile fresh milk so as to make suspensions containing material from 10 lice in each cc.

After the suspensions had been subjected to the usual laboratory tests a series of 10-fold dilutions were prepared in sterile skim milk, and 0.25 cc of each dilution was inoculated intraperitoneally into each of four cotton rats. Six of the suspensions were of lice which had fed on typhus patients who had been vaccinated against the disease and 10 were from non-vaccinated patients.

Each of the inoculated rats was challenged three weeks later with a dose of *Rickettsia prowazekii* 2-4 times the minimum needed to kill unprotected rats. The survival of a rat was regarded as showing that it had received at least one

viable rickettsiae in the inoculum. A calculation based on the degree of dilution that protected half of the inoculated rats of each group showed that on the average there were 10 viable rickettsiae in each cc. of louse suspension prepared from lice fed on the six patients who had been vaccinated, whereas there were 2,200 in each cc. originating from ten patients who had not been protected.

This striking difference was regarded as justifying the speculation that vaccination of a community with a Cox type vaccine followed by one or more "booster" doses of the vaccine would suffice to reduce sharply the development of an epidemic of typhus fever even if no measures of disinfection were employed.

The authors' study was already in progress when their attention was drawn to the report by WOLFE *et al.* which strongly supported the same view (see this Bulletin 1944 v. 41: 741).
 Job W. D. Meyer

WEYER, F. Versuche zur Uebertragung von Rickettsien auf Mäuseflöhe
 [Experiments in the Transmission of Rickettsiae to the Mouse Flea.] *Zent. f. Bakt. Abt. I Orig.* 1949 v. 153: 115-21

The author has found that the mouse flea (*Xenopsylla segnis*) readily becomes infected with *Rickettsia mooseri* and certain strains of *R. prowazeki* by feeding on infected mice and by intrarectal inoculation with infective material.

The technique of intrarectal inoculation of fleas is more difficult than in the case of lice.

As already described by the author in connection with experiments on other insects (this Bulletin 1949 v. 46: 624) intracellular strains of rickettsiae virulent for mice have often become extracellular and non-virulent after transfer through the flea and after transfers through lice. This change in the characteristics of the organisms is regarded as being due either to a true mutation or to the coexistence of extracellular and intracellular strains in the original infection, one or other strain becoming dominant according to the prevailing environmental conditions.

Fleas as well as ticks were found susceptible to the rickettsiae of Q fever and the author suggests that fleas may play a part in the transmission of the disease.

Job W. D. Meyer

RANDOLPH, R. M., O'DON, L. J. & EADES, R. B. Entomological Studies on Typhus in Lavaca County, Texas. *Texas Reports on B. & M.* 1948 v. 6 No. 4: 444-52. 9 figs.

This paper deals with the incidence of and the control by DDT in pyrethrin dust of certain flea-borne and mite parasites of *Rattus rattus* in urban and rural areas of Lavaca County, Texas during the period October 1945 to September 1946.

Throughout the year approximately 70 live rats per month from an untreated town and 10 rats per month from each of two treated towns were examined for ectoparasites. The treatments which consisted of dusting known and potential rat runs with 10 per cent DDT in pyrethrin dust at the rate of 1 lb. dust per small café or similar premises, 1 lb. dust per residence and 2 1/2 lb. dust per warehouse mill etc. were made in November, February and July. A similar study carried out in rural areas involved twenty long farms, 1 of which remained untreated while in eighteen the rat runs were dusted with 10 per cent DDT in pyrethrin dust at the rate of 1 lb. rat 1 lb. dust per farm. About three rats per farm were examined each month between April and September after apparently one application of dust.

Both *Xenopsylla cheopis* and *Leptopsylla segnis* showed significant reductions in the treated towns, but only the *X. cheopis* index was lower on the treated farms. There was no clearly detectable effect of the DDT on *Echinophaga gallinacea*, nor on the louse *Polyplax spinulosa*, nor on the mite *Liponyssus bacoti*.

The following additional ectoparasites are recorded from *Rattus rattus* — *Pulex irritans*, *Ctenocephalides felis* and *Nosopsyllus fasciatus*, and the mites *Echinolaclaps echidninus*, *Laelaps nuttalli*, *Eulaclaps stabularis*, *Dermanyssus gallinae* and *Atricholaclaps megaventralis*.

Fox, J P The Antibody Response of Rabbits to Rickettsial Vaccines in Water-in-Oil Emulsion *Amer J Hyg* 1949, May, v 49, No 3, 303-12, 2 figs [31 refs]

The incorporation of aqueous suspensions of various antigens in a water-in-oil emulsion has been found to enhance, and often to prolong, the antibody production resulting from the use of the antigens as vaccines.

Employing technical methods described in the paper the authors found that such vaccines, prepared from yolk-sac cultures of rickettsiae of epidemic and murine typhus and of Rocky Mountain spotted fever, caused great enhancement and prolongation of the complement-fixing and mouse-neutralizing antibody responses in the sera of vaccinated rabbits as compared with the responses obtained with aqueous-suspension vaccines.

The emulsion type of vaccine did not enhance the responses when tested on eastern cotton rats, and an emulsion type of murine vaccine did not give rise to a higher antibody production in man than the usual vaccines, though the antibodies persisted longer.

Vaccines prepared in the same way from *R. orientalis* gave rise to only a moderate resistance in guinea-pigs to challenge infection, and to no constant resistance in mice and cotton rats. The author states that more satisfactory protection might possibly result if a better original antigen could be obtained.

John W D Megaw

FOX, J P, RICKARD, E R, VAN DER SCHEER, J & COX, H R Antibody Response to Vaccination against Murine Typhus *Amer J Hyg* 1949, May, v 49, No 3, 321-39, 1 fig [41 refs]

The authors state that there are no published results of the use in man of murine-typhus vaccines of the yolk-sac type.

In the present study several types of vaccine were employed, all were derived from the same yolk-sac suspension. Each type was tested on groups of 19 to 25 persons, and altogether more than 400 persons were used in the tests.

Complement-fixation and rickettsia-agglutination tests were carried out before and after vaccination, the latter were found more sensitive than the former.

A single dose containing an adequate amount of antigen in the aqueous state gave results only slightly inferior to those resulting from the same amount of antigen given in three divided doses at intervals of one week.

Concentration of the vaccine by the sulphate or methanol method reduced the volume of the inoculum without affecting its potency. The water-in-oil emulsion [see Fox above] did not give rise to as high antibody titres as did the aqueous vaccine, but the immunity persisted longer. Vaccines precipitated by alum and zinc gave inferior responses. The responses to booster doses of the vaccines were much the same irrespective of the method employed in the primary vaccination, the responses were better 50 weeks after the primary vaccination than 22-28 weeks after.

John W D Megaw

A list of the hosts for each tick includes mice of the genera *Peromyscus*, *Microtus* and *Zapus*, skunk, opossum, rabbit, shrew, grey squirrel, *Rattus norvegicus*, red fox, cottontail, weasel, deer and chipmunk. The flying squirrel (*Glaucomys volans*) and the muskrat were not found to be infested with ticks. Birds (the brown-thrasher, cuckoo, catbird, song-sparrow, towhee and American thrasher) were parasitized only by *I. muris* and a few *I. leporis-palustris*. Some twenty other species of bird were found free of ticks.

Only *D. variabilis*, *I. dentatus* and *I. scapularis* were taken on man.

No adult ticks were found on birds and few on the mice, but many of the larger mammals carried both immature and adult ticks.

D. variabilis was the predominant species on the red fox (*L. ulpes fulvus*) and the raccoon (*Procyon lotor*). It was the principal tick occurring as adults on the fox. Its immature stages were found mainly on *Peromyscus leucopus* and *Microtus pennsylvanicus*. Instances are given of these ticks being numerous on grass around horse manure and a sheep's skull on the door of a pump-house and on the timber and grass of a boat slip in vicinities where it was otherwise not abundant. A larva with its rostrum inserted into a nymph engorging on *Peromyscus* is recorded.

Dragging a sheet across the ground yielded large catches of *D. variabilis* and a few specimens of *I. scapularis*, but all other species of tick were obtained only from their hosts. Although, therefore, *D. variabilis* would appear to be the most prevalent tick species when collections are made in this way, *I. muris* proved to be the predominant tick on many of the small mammals and birds.

In 1948, *D. variabilis* occurred in highest density on the red fox in May and June (35.8 and 23.0 adult ticks per host) while the infestation peak for *I. scapularis* on the fox was in April. Regional differences in the abundance of some of the tick species are discussed.

D. S. BERTS

BLANC G. & BRUYEAU J. "Un réservoir de virus de la Q-fièvre en Algérie: la tique bovine *Hyalomma marginatum*." [Natural Infection of the Bovine Tick, *Hyalomma marginatum* with the Rickettsia of Q Fever]. *Bull. Acad. Nat. Méd.* 1949 v. 133 No. 56: 115-17, 5 charts.

Using a pooled suspension of 17 of the common bovine ticks, *Hyalomma marginatum*, for the subcutaneous inoculation into the loin of guinea pigs the author isolated a strain of *Rickettsia burnetii*.

The ticks were collected at Maison Carrée in Algeria.

The two guinea pigs originally inoculated gave unusual reactions: there was slight fever within the first 4 hours accompanied by a hard haemorrhagic oedema and local lymphangitis at the site of the inoculation; there was only slight enlargement of the spleen. 1 guinea pig inoculated with spleen substance taken on the 6th day from the primarily inoculated guinea pigs there was a delayed febrile reaction and the animals became immune to an Algerian strain of Q fever rickettsiae. On further passages the reaction became typical and numerous rickettsiae were found in smears from the local lymph.

The authors express a preference for subcutaneous inoculation despite the need for further passages before rickettsiae can be detected in smears.

Joh. W. D. MEYER

PERRY T. L. "Histopathologic Observations in a Fatal Case of Q Fever." *Arch. Pathology* 1949 Apr. 47 No. 4: 361-3, 3 figs.

"Only six fatal cases of Q fever are on record, but see this *Bulletin* 1949 v. 46: 351 in which reference is made to seven deaths, mostly in old persons.

Autopsies are reported to have been carried out on four of the cases, but in these, as in the present case, lesions not connected with Q fever probably exerted an unfavourable influence on the course of the disease

In the present case, of a man aged 43, there was pronounced arteriosclerosis of the coronary artery and an old organized myocardial infarct. The lungs were in a state of bronchopneumonia with a predominantly mononuclear cell exudate and there was focal hypoplasia of the bone marrow, these were the only lesions regarded as being due to Q fever. In the areas of gross consolidation of the lungs most of the cells in the exudate were large mononuclears, there were a few neutrophile granulocytes and lymphocytes. In some patches there was a haemorrhagic exudate, and in many of the small isolated pneumonic areas neutrophile granulocytes predominated, but large mononuclears and lymphocytes also occurred in varying proportions *John W D Megaw*

HUEBNER, R J, JELLISON, W L, BECK, M D & WILCOX, F P. Q Fever Studies in Southern California. III. Effects of Pasteurization on Survival of *C burneti* in Naturally Infected Milk. *Pub Health Rep* Wash 1949, Apr 22, v 64, No 16, 499-511

By an extensive series of carefully controlled experiments it was shown that milk infected with *Coxiella* [*Rickettsia*] *burneti* became free from infection when pasteurized by the "high-temperature, short-time" method in which a minimum temperature of 160°F was maintained for 15 seconds.

With the "holding-vat" method in which a temperature of 143°F was maintained for 30 minutes the milk was freed from infection in three out of four experiments, in the case of failure it was found that three out of 20 guinea-pigs inoculated with the pasteurized milk gave positive complement-fixation reactions for Q fever.

Among 32 samples from bottles of vat-pasteurized milk on sale in the market it was found that three were presumably infected.

It is concluded that further work needs to be done to determine safe methods for eliminating the risk of infection by milk. *John W D Megaw*

YELLOW FEVER

CHWATT, L J. *Aedes* (*Stegomyia*) *pseudoafricanus* sp nov. a New Species of *Aedes* from the Coast of Nigeria (British West Africa). *Nature* 1949, May 21, 808-9

Of interest in relation to the precise identification of mosquitoes related to the yellow fever problem.

SMITHBURN, K C, HADDOW, A J & LUMSDEN, W H R. An Outbreak of Sylvan Yellow Fever in Uganda with *Aedes* (*Stegomyia*) *africanus* Theobald as Principal Vector and Insect Host of the Virus. *Ann Trop Med & Parasit* 1949, Apr, v 43, No 1, 74-89, 1 map [17 refs]

In previous papers [this *Bulletin*, 1947, v 44, 992] SMITHBURN and his colleagues described the results of investigations which indicated that yellow fever is endemic among monkeys in the Semliki Forest in Western Uganda and that *Aedes africanus* Theobald, which was found to be harbouring the virus, was the probable insect vector. The optimum biting level of this mosquito is at some distance above ground in the main forest-canopy, and its period of maximum biting activity is at a time when human beings are not often in the forest. Immunity studies in the human population showed a high rate of

infection among young children, who rarely enter the forest. The known vector of the disease among the human population in this area is *Aedes simpsoni* which occasionally enters the canopy of the forest edge.

In order to obtain further information on the mechanism of infection from animal to animal and to man, susceptible rhesus monkeys were exposed on plat forms in the forest canopy. In a previous paper [see this *Bulletin* 1949 v 46 457] the author and his colleagues described the infection of such a monkey at Zika, near Entebbe in 1947. From May to October 1948, infection with yellow fever occurred in monkeys in 4 of 9 stations in one area of the forest covering several square miles. No infections occurred in the same period among monkeys at 20 other sentinel posts in the Semliki Forest.

During the period July to October *Aedes africanus* caught in the forest canopy, were found to harbour virus, and when some lots were allowed to feed on normal monkeys, the latter became infected with yellow fever virus.

The monkey which received an injection of 133 *Phlebotomus* of various species caught in the first week of July in the same area, developed yellow fever at least 34 days later. The injection of suspensions of 4,234 other mosquitoes and 1,024 insects other than *Phlebotomus* spp. into a total of 10 non-immune monkeys gave rise to no infection.

RABIES

NOTICER R. Contribution to the Study of Bovine Paralytic Rabies in Venezuela. *Canad. J. Comp. Med.* 1947 Nov v 11 No. 11 335-7

First described in Brazil in 1911 paralytic rabies of cattle is a communicable disease which today affects most countries in South America and which as established between 1871 and 1899 is transmitted by blood-sucking bats. As a result of heavy losses among cattle in 1938, the Government of Venezuela began taking energetic measures to control the spread of the infection. Among these measures the principal was the vaccination of cattle in the areas involved. Inasmuch as the causal agent of the condition was found to possess certain biological and immunological characteristics which the virus of canine rabies lacked, two strains of the local paralytic virus were chosen for the production of vaccine and, after fixation, used in calves from 6 to 9 months old to ensure adequate supplies. The strains employed were (1) the Bolivar virus originating in the southern parts of Venezuela, from the State of Bolivar and (2) the Maturin virus deriving from the area where paralytic rabies of cattle was originally diagnosed in the country in 1938. The incubation period of the former strain became fixed for calves at 5 days on and after the 52nd passage; that of the latter at 6 days on and after the 14th passage. Both viruses in a dilution of 1 in 5,000 are lethal for the calf.

The finished vaccine is a 15 per cent emulsion of brain and spinal cord, the virus being inactivated by exposure to the action of phenol and heat at 37°C. As assessed by the Habel mouse test the antigenic potency is invariably higher than that required for a standard anti-rabies vaccine in the U.S.A. Moreover the vaccine has been shown to confer on mice better protection against the Bolivar virus than one containing Pasteur fixed virus.

In conclusion, paralytic rabies in Venezuela has been eradicated by satisfactory results. The disease is now under control and has ceased to be a veterinary problem because of the present vaccination of all susceptible animals.

G. Stuart

IONESCO, D Recherches sur la maladie d'Aujeszký [Investigations on Aujeszký's Disease] *Arch Roumaines Path Expér et Microbiol* 1948, v 15, Nos 1/2, 122-34, 1 fig [20 refs]

The English summary appended to the paper is as follows —

"A new virus 'AUJESZKY' was identified from a cat, with incubation period of 2 days in rabbit and guinea-pig By rubbing the shaved skin of young dogs especially, vesicles appear which very rapidly change into pustules and finally are covered by crusts These vesicles are produced with this virus and another virus AUJESZKY Nr 1, identified by the author in 1934

"The production of these vesicles creates immunity in dogs, immunity ascertained by the virulicidal action of blood serum (1/5) and by resistance to new infection

"There does not exist a cross immunity between AUJESZKY's disease and rabies

"Acquired immunity in dogs, due to friction or scarification of skin with formation of vesicles, obliges us to consider the AUJESZKY virus close to the herpetic virus and to add to the known neuro-organotrope characters of the virus, a new dermatrope character"

PLAGUE

ROCKENMACHER, M Relationship of Catalase Activity to Virulence in *Pasteurella pestis* *Proc Soc Exper Biol & Med* 1949, May, v 71, No 1, 99-101

"1 Optimal conditions for catalase activity in *P. pestis* were determined and the catalase activity of 14 virulent and 11 avirulent strains was measured

"2 The catalase activity of virulent strains was significantly greater than that of the avirulent strains

"3 The possibility of using catalase activity as a screening test for determining virulence *in vitro* has been indicated"

DAVIS, D E & FALES, W T The Distribution of Rats in Baltimore, Maryland *Amer J Hyg* 1949, May, v 49, No 3, 247-54, 4 figs

The survey described in this paper deals only with the census of brown rats (*Rattus norvegicus*) in Baltimore The roof rats (*R. rattus*) were far less common The basis on which the number of rats was estimated is stated as "an evaluation of the signs of rats in yards and houses and calibration with the number of rats trapped" It is assumed that this method has an error of about 10 to 20 per cent In the actual census a "trained observer examined the block for signs of rats, such as holes, droppings, runways Since in most cases these signs are located along the alley or can be seen easily from the alley, it was possible, therefore, merely to go along the alley to make the estimate The construction in some blocks was such that as good an estimate could be obtained from a car as by walking, in these cases the trained observer drove slowly along the alley"

In September, 1947, a random sample of 359 blocks was surveyed in the residential part of Baltimore and it was estimated that the total number of rats was between 119,000 and 158,000 On the basis of other sources of information it was estimated that there were about 26,000 rats in the commercial areas of the city The number of rats in each residential section varied directly with the number of houses needing major repairs

The wide range of variation in the rat population is shown by the estimate that in 156 blocks no rats were detected. In 181 blocks there were 5 to 73 rats and in 22 blocks there were 100 to 200.

The average number of rats in each dwelling unit was 0.583, the range in the different census tracts being 0.071 to 1.405.

In a previous estimate made in 1944 by a different method, the total number of rats was believed to be about 420,000, so that although the figures are not strictly comparable there must have been a considerable decrease since that time. This is attributed to extensive rat-proofing, poisoning, and better disposal of garbage and refuse.

The present human population of Baltimore is not stated, but it appears to be about one million because it is mentioned that even if there were 200,000 rats in the city this would mean at most one rat per five persons.

CHOLERA

GAULD R. L., SCHLIKOVAN A. S., JACKSON Elizabeth B., MANNING Mary C., BATEON H. C. & CAMPBELL, Charlotte C. Chloramphenicol (Chloromycetin) in Experimental Cholera Infections. *J. Bacteriology* 1949 Mar. v 57 No. 3, 349-52.

The results are submitted together of studies on the action of chloramphenicol (Chloromycetin) on experimental cholera infections which were carried out at the Army Medical Department Research and Graduate School, Washington D.C. and at the Research Laboratories of Parke Davis & Co., Detroit Michigan.

In vitro tests showed the drug to inhibit completely the growth of Inaba and Ogawa strains of *V. cholerae* in a concentration of 0.005 mgm./ml. of single strength brain heart infusion broth at pH 7.6. 50 per cent. inhibition as determined by turbidimetric assay was obtained with 0.00025 mgm./ml.

White mice were used for tests in which the drug was administered at various periods before and after an intraperitoneal challenging dose of a suspension of a culture in 5 per cent. hog gastric mucin. Several levels of dosage were employed. At Washington, in one series of tests in which the drug was given subcutaneously at periods from 1 hour preceding the challenging dose to 4 hours after there were only 2 deaths in 60 mice compared with 50 deaths in 60 untreated controls. Administration 6 hours after was not effective. At Detroit tests were carried out with chloramphenicol and sulphadiazine administered by stomach cannulae 1 and 6 hours after infection. Of those given chloramphenicol only 3 out of 170 died. In the sulphadiazine series 25 out of 60 died and in the control, untreated, group 22 out of 30.

A single dose of chloramphenicol at 4 hours after infection was also found effective: only 3 out of 178 mice dying after dosage 10.5 to 20 mgm. against 17 out of 30 controls. Sulphadiazine had considerable but lower value.

A single dose of chloramphenicol 4 hours after infection had little beneficial effect.

In discussing the findings in relation to their application to the treatment of human cases of cholera the authors remark that "No chemotherapeutic drug could be expected to be effective in this disease in man once dehydration had occurred unless it was augmented by measures designed to restore water, salt and protein balance. In the experiments in Detroit, chloromycetin was effective when given directly into the stomach of the mice. However, the vomiting in human cholera might well exclude the administration of the drug *per os* and it would probably be necessary to give it parenterally. Because of the extremely rapid development of this disease in man chloromycetin treatment would have to be instituted early. Indeed it is possible that if this drug proves to be of any value in the human disease its principal use may be as a prophylactic agent in the face of an epidemic."

[This recognition of factors which may affect the chemotherapy of cholera is timely. The same considerations are likely to apply in the case of other drugs that may be tried. A clinical trial to determine the actual field of usefulness of the drug, is however, desirable.]

SHRIVASTAVA, D L, SINGH, G & AHUJA, M L. Immuno-Chemical Studies of *Vibrio cholerae*. A Preliminary Note. *Indian J Med Res* 1948, Oct, v 36, No 4, 409-13 [14 refs]

Protection experiments against intraperitoneal infection of mice with *V. cholerae* were carried out with polysaccharides extracted from the organism by three different methods. The methods of extraction used were (1) WHITE's method [this *Bulletin*, 1936, v 33, 861] in which the growth on agar is digested with papain at 60°C and the protein subsequently removed by treatment with saturated picric acid solution, (2) SHRIVASTAVA and SEAL's method [*ibid*, 1937, v 34, 784] of treatment of the concentrate from broth, and removal of the protein by shaking with chloroform and butyl or amyl alcohol, and (3) the phenol method (PALMER and GERLOUGH, *Science*, 1940, Aug 16, 155) in which the acetone dried growth is treated with 90 per cent phenol.

White mice were immunized with two doses of 0.2 cc of a saline solution of the particular polysaccharide given at intervals of one week and a challenging measured dose of a six-hour culture of a selected strain of *V. cholerae* was given in 5 per cent mucin one week later. The total immunizing dose employed in different tests varied from 0.059 to 0.300 mgm of the polysaccharide.

The best results were obtained with the extract prepared by the phenol method, of which the details are given in the paper. The immunized animals were able to withstand a test infection of at least 200 lethal (L50) challenge doses. The results compared favourably with those obtained in controls given the ordinary type of cholera vaccine [the reference to WHITE is incorrectly shown as p 157, instead of p 229].

BOSE, H N & CHAKRABORTY, D C. Bactericidal Action of Metallic Copper on *Vibrio cholerae*. *Ann Biochem & Exper Med Calcutta*, 1948, v 8, Nos 3/4, 83-8.

The action of metallic copper on *Vibrio cholerae* was tested by placing strips of copper foil in suspensions of the organism in water and subsequently subculturing at intervals of half an hour. In distilled water, the vibrio could not be recovered later than 1-hour in the presence of copper, while it survived for 48 hours in controls. In filtered tank water with a nitrogen content of 0.4 mgm per 100 cc it could not be recovered later than 1½ hours but survived for 15 days in the absence of copper. Other intestinal organisms survived for longer periods.

When the copper foil was allowed a period of 2 hours contact with water and was then removed before the addition of the vibrio suspension, the organism could not be recovered later than 30 minutes. When contact had been for 4 hours, survival was for 15 minutes only. Other tests showed that the surface area of the copper foil in relation to the volume of water appeared to affect the rapidity of death of the vibrio. A higher nitrogen content of the water lengthened its survival.

When peptone water or Douglas broth were prepared with distilled water kept in contact with copper foil for 48 hours, no lethal effect on *V. cholerae* was shown, the organism still being recovered after 15 days.

Tests carried out in highly polished copper vessels instead of by addition of copper foil also showed lethal effect on the vibrio which could not be recovered from filtered tank water later than 1½ hours. The periods for other intestinal organisms were longer. In these experiments chemical tests for copper were negative.

It is suggested that water should be stored in clean copper vessels for 4 to 6 hours during periods of epidemic cholera.

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

VIEREMA, H. J. & KIAM, L. P. Enkele gevallen van amoebiasis. [Some Cases of Amoebiasis.] *Viertel Tijdschr. v. Geneesk.* 1949 June 25 v. 83 (a) No. 28 7143-6. [Refs. in footnotes.]

The English summary appended to the paper is as follows:—

"Four cases of amoebiasis, two of which autochthonous are described. One of the patients had a colon carcinoma as well whilst one of the others had a liver abscess when admitted. In two cases the nature of the disease had been misjudged for years.

Amoebic dysentery in the Netherlands is usually of tropical origin, directly or indirectly. Therefore the repatriation of tens of thousands of civilians after the war and the return of our troops from Indonesia are expected to give rise to an increase in amoebiasis. In this connection the importance of faeces examination is stressed. The significance of HUGHES and SATTLERGRUBER'S view on the commensal phase of *E. dysenteriae* (minuta forms) is explained, as well as the necessity of completing the smeltzer treatment with a course of yatrien (chinfofon or anayodin).

REARSON, LUCY V. & BARTGIS, IDA L. The Cultivation of the Small Race of *Entamoeba histolytica* with a Single Species of Bacteria. Research Notes.] *J. Parasitology* 1949 Apr. v. 35 No. 1, 718-19.

Ten tubes of Locke-egg medium containing rice-starch and bacteria ("organism 1") were seeded with 10 cysts each of small race of *Entamoeba histolytica* isolated by micro-manipulation from the stool of a patient with a symptomless infection. Seven of the 10 tubes became positive and one of these has been maintained for a year in sub-cultures. The original infection and the cultures were proved to belong to the small race of the organism. Cysts measured 7 µ and the trophozoites of the cultures 7-9 µ.

An interesting effect of the amoeba upon the rice grains was noticed. If particles are ordinarily enveloped in gluten, and few discrete grains are visible when growth of the amoebae begins, much of the gluten disappears and

profusion of discrete granules is left. This phenomenon is thought to be the result of the action of an enzyme derived from the amoebae which liberates the starch grains from their gluten envelope [see also this *Bulletin*, 1948, v 45, 517, 787] *P C C Garnham*

GRIFFIN, A M & McCARTEN, W G. Some Methods for the Quantitative Study of Entozoic Amoebae in Cultures. *J Parasitology* 1949, Apr, v 35, No 2, 193-8

A method has been devised to facilitate the counting of amoebae in cultures. Counts are performed in a cerebrospinal fluid counting chamber 0.2 mm deep with the Fuchs-Rosenthal ruling. The amoebae are grown in liver-serum-broth (10 cc) with purified rice starch (25 mgm). This rice is prepared very carefully in order to get rid of extraneous material, it consists of individual grains and suspends uniformly. The medium is inoculated with the amoebae, incubated and after an optimum period 20 mgm more of starch are added, followed by further incubation for 1 hour to permit the amoebae to gorge themselves. The sediment is suspended by "snapping" the tube or by aspiration with a pipette, 1 cc of 10 per cent formalin is added and the mixture is heated for 10 minutes at 70°C. The amoebae are again suspended and a sample is taken for a count. It may be necessary to centrifuge the fluid, if the culture is too sparse.

Experiments showed that this treatment with formalin followed by heat was the only satisfactory method to render the starch invisible and thus permit of easy counting of the organisms. These treated cultures could be stored and counted at any convenient time later. The manipulations result in the loss of some of the amoebae, amounting in some instances to 25 per cent but the relative counts are said to remain constant. *P C C Garnham*

BEAVER, P C & DESCHAMPS, G. The Viability of *E histolytica* Cysts in Soil. *Amer J Trop Med* 1949, Mar, v 29, No 2, 189-91

It is generally held that pollution of the soil with human faeces containing cysts of *Entamoeba histolytica* is one of the sources of amoebic infection. However, no observations have been made on the survival of the cysts in the soil. In the present paper the authors record experiments on the viability of these cysts, carried out in Venezuela.

Cysts, obtained from stools of carriers, were washed by repeated centrifugation in distilled water, after which the sediment was rinsed on to samples of damp soil kept in glass cylinders (15×15 cm) and worked to the depth of 10-15 mm from the surface. As a control, cysts concentrated by zinc sulphate flotation were washed and kept in 125 cc flasks with well aerated distilled water. At intervals of 2 days samples of the soil were suspended in distilled water, strained through gauze, concentrated by flotation, rewashed and inoculated in BALAMUTH and SANDZA's culture medium, [this *Bulletin*, 1945, v 42, 999], to test for the presence of viable cysts. At the same time cultures were made of the control cysts. The cultures were examined 24 and 28 hours after inoculation, those found negative on first examination were subinoculated in fresh medium and re-examined.

Five preliminary tests showed that cysts of *E histolytica* could be recovered from the soil by zinc sulphate flotation, that they remained viable in the soil at least 2 days, and that free-living amoebae will not grow in this culture medium at 37.5°C. In three other tests the results were negative, but cultures of the cysts made directly from the stools indicated that the cysts were already not viable, when deposited in the soil. It was also evident that some types of

soil used and a high external temperature (28-34 C.) did not favour the survival of the cysts. The soil used most successfully was dark loam containing over 30-40 per cent. of fine sand. The best results were obtained in three experiments in which cultures of *E. histolytica* with abundant growth were positive after 2, 4, 6 and 8 days. On the other hand in the control tests with aerated water growth in cultures occurred only after 2-4 days. It was thus shown that under certain conditions cysts of *E. histolytica* can survive in soil up to 8 days whereas in clean aerated water their viability does not exceed 4 days.

BEAVER, P. C. & DRACHMANS, G. The Effect of Acetic Acid on the Viability of *Entamoeba histolytica* Cysts. *Amer. J. Trop. Med.* 1949 Mar v 29 No. 2, 193-7 (10 refs.)

In view of the danger of amoebic infection arising from consumption of uncooked foods especially vegetables, the authors set themselves to find a prophylactic chemical which while lethal to *Entamoeba histolytica* cysts after short exposure would be non-deleterious to health, and would not adversely affect the appearance and flavour of the food. They have produced experimental evidence indicating that acetic acid in concentrations used in vinegar (about 5 per cent.) fulfils these requirements.

The tests conducted in Talara Peru, were carried out as follows. Specimens of stools from known carriers of *E. histolytica* containing numerous cysts, were washed repeatedly by centrifugation in distilled water after which the washed sediment was placed in test tubes (about 0.02 cc. in each). Various concentrations of the acid were added so as almost to fill the tube and the contents were mixed by rotation and shaking. At the end of the test period the tubes were centrifuged, the acid was poured off and the sediment was washed repeatedly. Viability of the cysts after treatment was determined by adding to the sediment BALAMUTH and SANDZ's all-liquid culture medium (this *Bullet.* 1945 v 4, p. 999). Cultures were examined after incubation for 36-48 hours and were reported as negative if no amoebae could be found after systematic search of one drop of the sediment. All negative cultures were subinoculated in fresh media. Untreated washed cysts served as controls.

The results of the tests were as follows. A 10 per cent. solution of acetic acid killed the cysts in less than 5 minutes; however this concentration cannot be used for vegetables because it wilts them rapidly and because vinegars containing this concentration are unpalatable. A 5 per cent. solution killed the cysts after treatment for 45 minutes but the time required was too long to be practicable. Finally a 3 per cent. solution was lethal to the cysts in 10-15 minutes, and this concentration would seem to be the most suitable for the treatment of vegetables. Except for radishes there was no change of colour in the vegetables while a change in the flavour of some vegetables did not differ from that acquired by them in salads.

Similar tests made with the local varieties of vinegar one containing 10 per cent. the other about 6 per cent. acetic acid, were in accord. Other tests showed that 70 per cent. citric acid and 21 per cent. lactic acid had no deleterious effect on the cysts.

It is concluded that since 15 minutes contact with 3 per cent. acetic acid kills not only the cysts of *E. histolytica* but also certain pathogenic bacteria (e.g. food poisoning staphylococci, *Shigella dysenteriae*, *Salmonella* etc.) it would appear to be well suited for chemical treatment of food.

STEWART, G T Nature of the Action of Emetine upon *Entamoeba histolytica*
[Correspondence] *Nature* 1949, May 28, 842, 1 chart

The author investigated the action of emetine hydrochloride on *Entamoeba histolytica* *in vitro*, (a) in cultures in horse serum and rice starch, and (b) in suspensions prepared from such cultures. Ten strains were used and the amoebae were accompanied by different bacterial flora (e.g., one strain was grown with *Bact coli* and *Cl welchii*). A dilution of above 10^{-7} of emetine had no effect on cultures, dilutions below this sterilized cultures in 3 to 7 days, while a dilution of 10^{-4} completely inhibited multiplication of the organisms. The addition of cysteine did not reverse the action of the emetine. Similar dilutions were employed on the suspensions, for the first four hours, the viability of the amoebae was unaffected (as shown by positive sub-cultures), but after this period, degeneration of the organisms began, and by 48 hours was complete.

The author concludes that emetine does not produce an immediate toxic effect upon *E. histolytica* but has an amoebostatic action proportional to its concentration. In fact, surviving amoebae removed after 48 hours from an emetine medium are able to grow normally. P C C Garriham

1 ARMSTRONG, T G, WILMOT, A J & ELSDON-DEW, R The Treatment of Amoebic Dysentery in the Bantu African *Trans Roy Soc Trop Med & Hyg* 1949, May, v 42, No 6, 597-604, 1 fig

11 —, ELSDON-DEW R & MAROT, R J Amoebiasis in the African. A Report on the Treatment of 600 Cases *South African Med J* 1949, May 14, v 23 No 20 369-74, 4 figs (1 coloured)

1 The substance of this paper, with some additional information and conclusions, is to be found in the paper reviewed below

11 Amoebic dysentery is a common and serious disease in male Africans, there were 2,500 admissions for it to the King Edward VIII hospital, Durban, in one year. The response to the usual amoebicides was poor, so tests were made of the efficacy of various drugs alone, or in combination, in the treatment of the condition. The assessment of results was based on immediate repeated examinations of the stools and of scrapings obtained sigmoidoscopically. "Probable successes" comprised those in whom both ulceration and parasites disappeared after treatment, "failures" included "absolute failures" in whom both persisted, and "possible failures" in whom ulcers persisted but amoebae could no longer be found. Follow-up over an adequate period was impracticable. Emetine and diodoquin, either being given alone, were found to produce "probable success" in only about 50 per cent of cases, and "absolute failure" followed in 28 per cent, together concurrently "probable success" was obtained in over 70 per cent, and "absolute failure" occurred in only 2 per cent. E B I produced results comparable to emetine, carbarsone was markedly inferior to diodoquin in efficacy.

Combined penicillin and sulphasuxidine treatment either for a week before emetine and diodoquin treatment, or concurrently, produced a very high percentage of "probable successes" (over 90 per cent of 105 cases), and sulphasuxidine only, with emetine and diodoquin, produced comparable results (88 per cent in 49 cases). Penicillin (6 million units) and sulphasuxidine (600 tablets) for 21 days, without any of the recognized amoebicides given to 11 cases resulted in "probable success" in 82 per cent, and no "absolute failures", the immediate effect was considered to be greater than that of emetine alone. The conclusion is reached that these "antibiotics" [penicillin and sulphasuxidine] are immediately effective in the treatment of amoebiasis.

ANGIONI, G. Iodoformio nella cura dell'infezione amebica. [Iodoform in the Treatment of Amoebiasis.] *Atti Med. Italiana*, 1949 Apr v 4 No 4 83-8. [1st refs.] English summary (5 lines)

Treatment of amoebiasis by iodoform was brought forward by CASTELLA in 1935 [this *Bulletin* 1936 v 33, 546] and since then several have written extolling its value alone or combined with emetine or alternating with emetine.

The author in this paper records the results of its use in 29 patients in different stages of the infection. The preparation used contained in each tablet 0.05 gm. of iodoform with vegetable charcoal 0.1 gm. Ext. of camomile 0.01 gm. and Ext. lactucae virosae (lettuce) 0.02 gm. with sugar and starch. The odour and taste of the iodoform are thus masked and the drug is well tolerated.

The patients, for purposes of description, were divided into three groups. (1) Nine who had had the infection for 15-20 months, had had other forms of treatment and were in a fair general state of health. These were given 30 cgm. (6 tablets) [presumably daily] for 1st consecutive days then, after an interval of 5 days, a second course of 15 cgm. daily for 10 days. The amoebae were not seen in the faeces after 6-8 days' treatment the general condition improved, abdominal pain diminished and stools were fewer. (2) Eleven in a fair condition generally who had been ill for two years or more and had had various forms of treatment. These were given 30 cgm. daily for 8 days, then a course of emetine (50-70 cgm. in all) followed by 15 cgm. of iodoform daily for 10 days. With one exception, the faeces were all negative for amoebae and remained so for 2 months (later events not mentioned). (3) Nine patients in bad general condition, with anaemia and myocardial complications and who had undergone treatment in various hospitals. These were given iodoform only 10 cgm. daily for 20 days, with a week's rest [whether during the course or after a course and before undergoing further treatment is not stated]. One of these is thought to have been cured, 5 improved, one was unchanged, one had been transferred elsewhere (and presumably could not be followed up) and one died of broncho-pneumonia. None of the patients showed any signs of intolerance.

HAWORTH, R. D. McKENNA, J. & SINGH, N. Constitution of Conessine. Part I. *J. Chem. Soc.* 1949 Apr 631-8 16g

MORETTI, G. F. Hépatite amébienne et conessine. (A propos d'une auto-observation.) [Auto-Observation regarding Amoebic Hepatitis and Conessine.] *Bull. Soc. Path. Exot.* 1949 v 44, Nos. 3/4 172-5.

The author himself suffered from an attack of amoebic hepatitis for which he was treated with conessine hydrochloride 0.5 gm. daily (total 1.5 gm.). By the third day the symptoms and signs of hepatitis had vanished. Another course of 2.20 gm. of the drug over five days was given a week after completion of the first. The toxic side-effects of treatment initially were sweats, giddiness, trembling, dryness of the mouth, and a bitter taste; during the second course these were less evident. Although chronic colitis persisted no amoebae or cysts were found in the stools after treatment.

RIOC in discussion reviewed the treatment of amoebiasis with the total alkaloids of *Holarrhena floribunda* and with the hydrochloride or the hydrobromide of conessine. He considered that the salts in the advocated high dosages produced side effects which precluded their general employment in ambulatory cases and in the G.I.T. The total alkaloid in smaller dosage proved as therapeutically satisfactory were better tolerated, and were therefore more suitable for ambulatory treatment.

PRADO, F., Jr. Ação dos extratos de *Jacarandá decurrens*, de *Nectandra pichury* e de *Simaruba officinalis* sobre *Entamoeba histolytica* [The Action of Carobinase on *Entamoeba histolytica*] *Brasil-Médico* 1949, Feb 5 & 12, v 63, Nos 6/7, 43-5 [14 refs] English summary

Carobinha is one of the local names of *Jacaranda decurrens*, a tree of Brazil, growing to a height of 4½-6 feet, whose leaves contain a bitter principle with astringent action, an aromatic balsam like coumarin, an acid, carobic acid, a bitter resin and a crystallizable glucoside. An extract obtained from the leaves (and also from *Nectandra pichury* and *Simaruba officinalis*) is known as Carobinase. An aqueous extract and a tincture of the fresh leaves were used by PECKOLT & PRADO in protozoal infections [see this *Bulletin*, 1935, v 32, 657]. [But the figures given in this paper and quoted from a thesis by Valdivieso in 1940 convey little useful information, since it is stated that "forty cases of dysentery were treated, with 86.5 per cent cures in acute forms and 80 per cent in the chronic forms" and that "magnificent results were obtained in 60 per cent of Trichomonas infections and 62 per cent of Giardia"]

The author has now tested, by way of preliminary to the use of carobinase in human cases of amoebic dysentery, dilutions of carobinase and their effect on cultures of *E. histolytica* at 37°C at pH 7.2-7.5. It was found to be amoebicidal in a strength of 1:4,000 and inhibited, but did not kill, at 1:5,000. It acted better, i.e., in higher dilution, in an alkalinized medium than in an acid, and it is advised that, if tried in man, alkalis should be given at the same time.

H. Harold Scott

CARINI, A. & REICHENOW, E. *Entamoeba caudata* n. sp. *Ztschr. f. Tropenmed. u. Parasit.* Stuttgart [1949], v 1, No 1, 102-5, 8 figs

The authors describe a new intestinal amoeba recovered from the stool of a dog. The living parasite was observed in São Paulo, Brazil, by one of the authors, who supplied the other with preparations stained with iron haematoxylin, on which the present study is based.

When seen alive the amoeba was actively motile, its movements resembling those of *Entamoeba histolytica*. This motility was registered in the permanent preparations which show amoebae extended in length, with a finger-like pseudopodium, or rounded, with several blunt pseudopodia. The amoebae varied considerably in size, from 10 μ in diameter to 36 μ × 16 μ , the majority measuring from 20 to 26 μ .

The structure of the nucleus is typical of the genus *Entamoeba*, being vesicular, with a karyosome, which may be central or eccentric, and with coarse peripheral chromatin granules which are irregularly distributed on the nuclear membrane, usually in groups. The cytoplasm contains numerous ingested bacteria. The most characteristic feature of the new amoeba is the presence of a sac-like rounded protrusion situated at the end of the body opposite to the direction of locomotion, on account of which it is referred to as the "caudal appendage" (*Schwanzanhang*). This appendage, which appears to be a constant structure independent of the rest of the body, frequently contains masses of darkly staining granules representing bacteria in different stages of digestion. The authors regard this structure as a localized organ of digestion. Although blood and mucus were seen in the stool of the host, no cellular elements were present in the stained preparations. Cysts of this amoeba have not been seen. All the features described are shown in the text figures accompanying this paper. On account of the presence of a special "caudal" appendage with digestive functions, the amoeba in question is referred to a new species under the name

Entamoeba candida. The only other amoebae in which there is a differentiated portion at one end of the body are the free living *Trichamoeba* and the avian parasite, *Pygidium*.

GATTNER H. Die Flagellateninfektion des Darms. [Flagellate Infections of the Intestine.] *Med. Abh.* 1949 Apr 1 v 44 No 13 400-404 6 figs.

There are two schools of opinion regarding intestinal flagellate infection one looks upon them as harmless commensals the other as definitely pathogenic. The author belongs to the latter school. There is a third, or perhaps we should say an intermediate school which holds that some other lesion is primary and enables the protozoon under normal conditions harmless to become pathogenic. The author quotes cases in which a watery diarrhoea was the common symptom, with loss of weight and, in those of long standing symptoms leading to a suspicion of pellagra or sprue. One case is referred to of a man who suffered for a year from nocturnal enuresis and was found to have a *Trichomonas* infection when this was got rid of the enuresis also cleared up. The parasites found were *Giardia intestinalis*, *Trichomonas intestinalis* and in one this last together with *Chilomastix mesnili*. Under appropriate treatment the symptoms disappeared. Atebrin [mepacrine] 0.1-0.2 gm. daily was given for *Giardia* infection for *Chilomastix* and *Trichomonas* calomel for os and enemas of 5 per cent. argyrol were given. The author also gave emetine 0.05 gm. subcutaneously daily with success in *Giardia* and *Trichomonas* infections, and for the latter stavarsol, methylene blue 0.1 gm. t.d.s. or gentian violet 0.1-0.5 gm. [In none of the cases recorded is anything said of re-examination of the faeces after treatment to prove whether with the improved general condition and relief of symptoms, the parasites disappeared or not.] H. Harold Scott

HARRIS, R. H. & MITCHELL, J. H. Chronic Urticaria due to *Giardia lamblia*. *Arch. Dermat. & Syph.* 1949 Mar v 59 No. 5 587 9 1 fig.

A case is presented of chronic urticaria of five months duration with evidence of *Giardia* infestation which cleared after administration of quinacrine hydrochloride for a few days. A subsequent examination of the stool showed no evidence of *Giardia lamblia*. The accompanying symptoms of nausea, epigastric distress and alternate constipation and diarrhea ceased.

BYLMEER J. *Tricercomonas intestinalis* in the Netherlands. *Documenta Neerlandica et Indonensis de Morbis Tropici*. Amsterdam, 1949 Mar v 1 No. 1 71-4 1 fig.

In a survey of the population of Holland for intestinal protozoa the author detected the presence of *Tricercomonas intestinalis* (= *E. crounensis hominis*) in cultures of stools obtained from four persons. The culture medium consisted of liver infusion agar and diluted Loeffle serum with the addition of rice starch in which the flagellate grew at 37°C. Examination of fresh and stained (iron haematoxylin) smears revealed in the flagellate the typical structure. Four flagella (which three are directed forwards and one runs along the side of the body terminating in a free end posteriorly. In general the structure of the flagellate agreed with that described originally by Weyro and O'Connor except for the nucleus in which the chromatin (chromosome) was situated on the nuclear membrane. In discussing the nomenclature of the flagellate the author adopts the name *Tricercomonas intestinalis* in preference to *Entamoeba hominis* by which it is more generally known at present. Since in the present

cases the flagellates were not observed in the stools directly but were recovered in culture, it is thought that the actual incidence of infection with this species is higher than existing records would lead one to suppose C A Hoare

RELAPSING FEVER AND OTHER SPIROCHAETOSSES

KRAKOWSKI, I & EDELSTEIN, A A Brief Survey of 25 Cases of Tick-borne Relapsing Fever, observed at No 9 Army Hospital Harefuah Jerusalem 1949, May 1, v 36, No 9 [In Hebrew 101-3 English summary 103]

"A benign disease caused by *Borrelia sogdianum*, a morphologically non-distinguishable strain of *Sp. obermeieri*. The cases were mostly of longer duration than is usually supposed, but of mild character and without any serious complications. The diagnosis was made by blood smears and 'thick drop' examinations. Contrary to the literature there was no leucocytosis and we observed at the time of the attack either a normal number of leucocytes or a relative leucopenia. An important diagnostic feature, which also could not be found in the classical or current literature is the high Blood Sedimentation Rate.

"Resistance of *B. sogdianum* to Salvarsan treatment.

"No active immunization because of probable different serological strains. There was no significant improvement or complete healing after penicillin treatment.

"No definite conclusions could be drawn concerning the prognostic value of the BSR.

"After surveying recent literature about local cases of relapsing fever and the occurrence of our cases, the conclusion might be drawn, that this disease is prevalent throughout the whole country."

BABUDIERI, B & BOCCIARELLI, D Electron-Microscope Studies on Relapsing Fever Spirochaetes *J Hygiene* 1948, Dec, v 46, No 4, 438-9, 10 figs on pl

This paper is a summary of observations, published by the authors in 1943 (*Rend Ist Sup. Sanità*, v 6, 305), on the morphology of relapsing fever spirochaetes as revealed by electron microscopy. One strain each of *Treponema recurrentis* and of *Trep. novyi* were used, the organisms being fixed in osmic acid vapour to avoid alterations during the repeated washings in the centrifuge.

Two forms of spirochaete were constantly present. One with both ends sharply pointed and a second with one pointed and one rounded end. During active reproduction the proportion of treponemes with both ends pointed rose sharply. It is suggested that the form with one rounded end is in the resting phase. Division takes place transversely by central thinning and results in one treponeme of each variety. If division is rapid, the rounded end does not develop, and subsequent divisions increase the sharp-ended forms still more.

The protoplasm appears to be homogeneous, but contains a few vacuoles and granules. No axial filament could be demonstrated. An undulating membrane, 0.05-0.1 μ in breadth, stretches the whole length of the spirochaete. If macerated, it forms fine fibres. In the rounded-end form, but never in the other, terminal flagella or a terminal filament were noted.

The authors consider that the presence of flagella and an undulating membrane bring the genus near to *Trypanosoma*.

[This should be compared with the paper on *Trep. vivax* by HAMPTON *et al.* (*Bulletin of Hygiene* 1949 v 24 444) the illustrations in which show many points of difference. There are 10 illustrations in the present paper]

DUBOIS A. Pluralité des souches de *Spirochaeta duttoni* dans une région limitée [The Plurality of Strains of *Spirochaeta duttoni* in a Limited Area.] *Ann. Soc. Belge de Méd. Trop.* 1949 Mar 31 v 29 No. 1 15-17

The author previously [this *Bulletin* 1931 v 28 735] showed that two strains of *Spirochaeta duttoni* isolated from different regions of the Congo, about 1 000 miles apart were immunologically distinct. The present note contains the results of a comparison of four strains of *S. duttoni* isolated from ticks and maintained in mice. Three strains came from one district of the Belgian Congo, Asirida, and one from Kigali only about 50 miles away. They were found to belong to two distinct types.

BLANC G. & MAURICE, A. Contribution à l'étude du spirochète de Goulamime (Maroc méridional). [A Contribution to the Study of the Goulamime Spirochaete (Southern Morocco).] *Arch. Inst. Pasteur à Maroc* 1949 v 3 No. 10 813-15.

Numerous ticks *Ornithodoros erraticus* were collected from the burrows of rodents in the region of Goulamime Southern Morocco and found to be infected with the spirochaete first recorded from this region by BALTAZARD [this *Bulletin* 1938, v 35 497]. The authors succeeded in producing infections in white mice and the Barbary ape (*Macaca sylvana*) and also found the spirochaete in the blood of the rodent living in the burrow, *Sitomys shawi*. Mice were found to be very susceptible and showed a heavy infection lasting in the blood up to 15 days. The Barbary apes were found to be much less susceptible to this strain than to the house-transmitted relapsing fever. Five inoculated with blood containing spirochaetes showed rare organisms in the circulation but no febrile symptoms and one bitten by infected ticks showed no signs of infection. Attempts to infect six human subjects in various ways gave negative results.

The authors provisionally suggest the name of *Spirochaeta (Berrelia) mercurialis* for this organism.

BALTAZARD M. KYDIAN B. MORIDI C. & BARHAYAR, M. Données expérimentales nouvelles sur la fièvre récurrente épidémique humaine [New Experimental Observations on the Epidemic of Human Relapsing Fever] *Bull. Acad. Nat. Méd.* 1949 v 133 Nos. 13-14 284-9 2 figs.

The authors summarize some of the information concerning the great pandemic of relapsing fever which started during the recent war and which, after lasting for more than five years, now seems to have died out. Fifteen different strains of the spirochaete have been isolated and studied in newly born rabbits this *Bulletin* 1947 v 44 805. Eleven were only maintained long enough for their identification, three were kept for some time in rabbits and lice and then abandoned, and only one strain isolated 31st May 1947 is still being maintained (29th March 1949).

This strain R 2 XVIII after 114 passages shows no alteration in its characters. The pathogenicity remains as low for experimental animals but it is still very virulent to man as shown by two accidental infections in the laboratory. It has also been used in the parent therapy of 23 cases of general paralysis for which it is very suitable. It is very susceptible to chemical treatment.

Very numerous experiments have been made on the louse transmission of the disease with the use of four different strains. The incubation period in man was found to range from 3 to 7 days, depending on the inoculum. Each strain was found to be antigenically distinct, and recovery from any strain, although conferring immunity against the same strain, did not give any protection against the other strains. The relapse spirochaetes were found to be identical with those of the primary attack.

Evidence is produced in support of the view that there is a seasonal cycle in the virulence of this infection in man. During autumn the virulence diminished and in winter completely disappeared, although in young rabbits and lice the virulence remained unchanged. In April, however, the strain was found to have recovered its full virulence which was maintained until the next autumn when the same diminution and disappearance of infectivity to man was repeated.

Concerning evolution in the louse, the authors find that at 32°C spirochaetes, as such, disappear in 24 to 36 hours, on the sixth, seventh and eighth days, short forms begin to appear, and become more abundant in the following days. During the negative phase the contents of the lice were still virulent. Lice were found to retain their infectivity as long as they lived, a maximum of 23 days in this series of experiments. The percentage of lice becoming infected after feeding on blood containing spirochaetes seemed to depend on the intensity of the infection, and similarly the intensity of infection depends on the number of spirochaetes in the louse. All the negative results were considered to be due to the ingestion of too few spirochaetes, and the authors were unable to infect any lice by feeding them on human cases in the autumn when the virulence was diminishing.

- 1 BALTEANU, I, RUSS, M & VOICULESCU, M. Les propriétés spirochétolytiques du sérum de convalescent de fièvre récurrente [Lytic Properties on Spirochaetes of Convalescent Serum from Cases of Relapsing Fever] *Arch Roumaines Path Expér et Microbiol* 1948, v 15, Nos 1/2, 310-12
- 11 —, VOICULESCU, M & RUSS, M. L'action thérapeutique du sérum de convalescent dans la fièvre récurrente [Therapeutic Action of Convalescent Serum in Relapsing Fever] *Ibid*, 312-15

1 In louse-borne relapsing fever, antibodies appear and reach their maximum titre during convalescence. Serum from such cases, when mixed with complement and added to a suspension of spirochaetes, causes granular fragmentation and eventually disappearance of the spirochaetes *in vitro*.

During an epidemic of the disease in Bucharest in 1946, convalescent serum was used in treatment [see below]. This note records a study of the action of the serum *in vivo*.

The authors were struck by the strong and rapid reaction ($\frac{1}{2}$ to $\frac{1}{4}$ hr) which followed the intravenous administration of convalescent serum to patients during an actual attack. The violent rigor, hyperpyrexia, and aggravation of symptoms—even actual collapse—were followed by quick defervescence and cure in three-quarters of the cases. When intravenous therapy was replaced by intramuscular the reaction was fairly light and resembled normal defervescence. The spirochaetes disappeared from the blood in 3 to 12 hours.

The authors believed that this *in vivo* result corresponded to the *in vitro* destruction of spirochaetes, and was attributable to the presence of products of protein breakdown. They liken the reaction to a rather violent Herxheimer reaction.

Experiments showed that no such reaction followed the intravenous inoculation of (1) relapsing fever convalescent serum into two patients with other acute fevers, (2) normal serum in patients during an attack of relapsing fever (3) convalescent serum in three patients during the afebrile stage of relapsing fever.

They therefore conclude that (1) The therapeutic action of the convalescent serum is specific and due to its "spirochaetolytic" properties, (2) it only occurs when the serum is given during the febrile period, when the patient's blood is rich in spirochaetes.

ii. During the great epidemic of house-borne relapsing fever in North Africa in 1914-45 [this *Bulletin* 1946 v. 43 829] convalescent serum was used in treatment with favourable results by a number of workers e.g. HOFFMANN and WEICHRODT and BEXILAMON (but no references are given).

The present authors treated 30 patients in this way in Bucharest between January and July 1946. They give examples of conditions when such treatment is specially indicated e.g. when arsenical treatment is contra-indicated, not available or ineffective. It is noted that 75 per cent of relapses followed treatment by salvarsan of Rumanian prisoners having nutritional deficiency.

The serum has the advantage of being free from "toxicity" properly so-called (but see above). It can also correct the hypoproteinaemia often seen in relapsing fever and it is readily obtained on the spot during an epidemic.

The serum was obtained from patients with no previous treatment, from the seventh day of apyrexia after the third febrile attack. 1 general sera were chosen having a minimum spirochaetolytic titre of 1/1 000. After bacteriological control, pooled sera from several convalescents were kept in the refrigerator.

After the severe reactions first encountered in intravenous therapy this was abandoned in favour of the intramuscular route. The total dose varied from 50 to 120 cc., being in general 1 cc. per kilo of body weight. Doses exceeding 50 cc. were given in two injections at an interval of two days.

The first 10 patients served to establish the most suitable form of technique. Of the other 20 15 were inoculated during the first attack. 14 of these were cured and only 3 had second attacks. Among 24 untreated controls only 8.3 per cent. had another single febrile attack, 41 per cent. had two attacks, 41 per cent. had three and 7 per cent. had four.

In those patients treated with serum the duration of the first attack was 5.65 days, compared with 5.92 to 6.83 days in the controls. It was clear that the treatment arrested the development of the disease which in four fifths of the cases showed only one relapse of reduced duration.

Therapeutic efficacy was directly proportionate to the quantity of serum given. The best results were obtained with the use of 80-120 cc. given in two injections at intervals of 4 hours. This resulted in cure in all 18 patients while only 4 out of the other 7 were benefited by doses of 50-65 cc.

It is stated that the best time for starting treatment is during the first febrile attack.

YAWS

COSTHUIZEN, S F Yaws. *Brit J Radiol* 1949, May, v 22, No 257, 276-9, 7 figs

Bone lesions occur in the tertiary stage of yaws, the secondary skin lesions of which usually occur in childhood. Bones are affected in the following order of frequency: tibia, inner end of clavicle, upper limbs, hands, feet and skull. It is uncertain if the vertebral column is affected, but the author refers to cases in which this might have happened. The periostitis and osteitis of yaws resemble those of syphilis. Pain is prominent in the lesions of the long bones, but not in those of the skull, in which swelling is the chief complaint and in which pressure symptoms may occur. Although symptoms are rapidly relieved by arsenical or bismuth therapy, "these drugs provide no cure, they merely give temporary relief."

The author describes (1) periosteal changes producing "onion-peel" or lace-work patterns and the production of sabre tibia, (2) erosion of cortex, usually multiple and with well-defined margins, (3) cyst-like changes, especially in the skull, (4) sclerosis often related to (1) and (2), (5) sequestrum formation, particularly in hands and feet, (6) changes in contour of bones. Joints are not usually involved. Differentiation from syphilitic bone lesions may be very difficult.

[There is no indication of the country of origin of the lesions described, clinical or serological data upon which diagnosis was based, or the number of cases upon which the author's generalizations are based. One would like to know his reason for the conclusion that the effects of arsenical and bismuth therapy are merely palliative. No reference is made to secondary bone lesions, especially in children, which are probably more frequent in many parts of Africa than tertiary bone lesions in adults. There are no references to any publication on the bone lesions of yaws. see this *Bulletin*, 1946, v 43, 1091.]

C J Hackett

FRIEDHEIM, E A H A Five Day Peroral Treatment of Yaws with STB, a New Trivalent Arsenical *Amer J Trop Med* 1949, Mar v 29, No 2, 185-8

The author discusses the essential characters of the ideal drug for the treatment of yaws in rural populations. They are, wide safety margin, ease of administration, short course of treatment, stability under tropical conditions and low cost. "We have now prepared a relatively non-toxic and stable form of 4-oxy-3-acetylaminophenylarsenoxide, i.e., the trivalent derivative of acetarsone [acetarsol], and find that this compound, designated 'STB' approaches closely the characteristics set forth as being desirable for mass treatment in undeveloped territories."

Clinical tests were made in mountainous forest regions of Gueckedou, French Guinea, in 88 cases of secondary yaws. The daily dose used was "0.01-0.02 gr" [presumably gramme] per kgm body weight by mouth in single doses on five consecutive days. No signs of intolerance were observed. Patients were observed for three months, when 87 of the 88 patients were regarded as cured [presumably on clinical evidence only as no serological data are reported].

[A number of statements are made, such as "Tartar emetic has had to be banned altogether from use in the Kissi tribe of Sierra Leone, where even greatly reduced doses caused death," for which no authority is given by the author or known by the reviewer.]

LEPROSY

CANIZAROS O. New Official Classification of Leprosy. *Arch. Dermal. & Syph.* 1949 May v 59 No. 5 584-8

The author discusses the findings of the 5th International Congress for Leprosy held in Havana, Cuba, in April 1948 (this *Bulletin* 1949 v 48 52) with special reference to the superiority of sulphones in treatment and to the new classification which will supersede the Cairo classification.

As the recommendations of the Classification Committee of the Congress have not yet been published in detail in this *Bulletin* the relevant text of their Report is reproduced here in full —

The Classification Committee of this Congress in a serious attempt to reconcile and unify these apparently discordant systems has arrived at a formula which is believed to be based on a biologic interpretation of the clinical facts. The criteria on the basis of which the three classes herein defined are established are in diminishing order of availability: (1) clinical, (2) bacteriological, (3) immunological, and (4) histopathological.

It is proposed that the classical division of leprosy into two types, polar (Raballo 1938) in their essential characteristics and relatively stable in their evolution, be recognized and maintained and that they be designated:

"*Lepromatous* (malignant or gravis) symbol L.

"*Tuberculoid* (benign, or mitis) symbol T.

It is also proposed that in addition recognition be given a group of cases of less distinctive or positive characteristics less stable and less certain with respect to evolution, and that it be designated *Indeterminate* (undifferentiated) symbol I.

Definitions

The characteristics of these three classes of leprosy are as follows —

"*Lepromatous type*: Minimal resistance to the existence, multiplication and dissemination of the bacilli; constant presence of large numbers of bacilli in the lesions with a distinctive tendency to form globi; characteristic clinical manifestations in the skin, mucous membranes (especially of the upper respiratory tract and eye) and of the peripheral nerves, together with involvement of other organs; regular failure to react to lepromin; pathognomonic granulomatous structure of the lesions; marked stability of type and tendency to progression. These cases are infectious or open.

"*Tuberculoid type*: High resistance to the existence, multiplication and dissemination of the bacilli; bacteriologically negative as a rule or if positive with few bacilli except in reactional states; characteristic clinical manifestations mainly in the skin and nerves, tending to be limited in extent and varying in degree with the reactivity of the tissue; reactivity to lepromin in very high percentage of cases; nearly always a tuberculoid granulomatous structure in active lesions; marked stability and a strong tendency to spontaneous regression in the absence of repeated reactions. These cases are usually non-infectious or closed.

"*Indeterminate group*: Variable with respect to resistance, clinical manifestations chiefly in the skin and nerves; the skin lesions usually flat macules either hypochromic, erythematous-hypochromic or erythematous; bacteriologically negative as a rule or if positive with few bacilli; lepromin reaction usually negative or moderately positive; the lesions histologically of simple inflammatory nature; stability much less than in either of the polar types and variable tendency with regard to persistence, progression or regression or transformation into one of the polar types. These cases are usually non-infectious.

" Clinical Subdivision of Cases

" The fundamental aim of any classification of a leprosy case being the determination of the type or group to which it belongs, in accordance with the foregoing definitions, certain members of the Classification Committee held that the 'subtypes' of other systems merely correspond to clinical aspects of variable importance. These aspects can be considered from different points of view, namely —

" *Degree of severity* (as, for example, the I_1 , L_2 , L_3 , of the Memorial Conference classification),

" *Manner of evolution* (slow or rapid, stationary or progressive, reactionary states, etc.),

" *Localization* (skin, nerve, eye, systemic, etc.),

" *Morphology* (macules, nodules, 'plaques', diffuse infiltrations, etc.),

" *Clinical form* (classical nodular lepromatous, diffuse lepromatosis of Lucio, etc.)"

H J O'D Burke-Gaffney

QUEENSLAND ANNUAL REPORT ON THE HEALTH AND MEDICAL SERVICES
OF THE STATE OF QUEENSLAND FOR THE YEAR 1947-48 pp 7-8 Leprosy
[REYE, E J & MAHONY, F]

In Queensland there were 52 white patients with leprosy on Peel Island at the end of June, 1948 of whom 42 were males. The average age was 47 years and there were six over 70. There were three deaths from intercurrent disease. All patients co-operating received sulphone therapy. It is stated that prominin therapy was 'highly satisfactory in view of the fact that a number of cases receiving it were in a very serious condition and that at the end of twelve months all were out of danger'. Nevertheless the use of this drug was abandoned in view of the time required for its administration. Fourteen patients completed the full year's treatment and 12 others received 6 months' treatment each.

The administration of diasone was easier, as it is given by the mouth. It was given to those not on prominin in November, 1947, and to those who had been on prominin for a full year. The results have "so far been quite satisfactory". No transfusions were necessary, any anaemia occurring being amenable to ordinary measures. There was one case of severe granulopenia which responded to pentosenucleotide, penicillin and liver extract.

Diasone treatment was continued by discharged patients under the supervision of their own doctors. It is hoped eventually that this treatment will be available for most of those patients on parole and for those in the non-infectious stages.

No surveys among aboriginals were possible, but there was "a number of admissions to Fantome Island during the year" among cases suspected in the last survey.

The difficulties of diagnosis, and the shorter periods of contact and incubation in aboriginals are discussed and the need for thorough and extended examination of known contacts is stressed. "The present state of the disease in Queensland remains virtually unknown".

Great improvements in the general amenities at Peel Island are recorded, especially as regards conversion of Army huts into additional accommodation and the introduction of an electric light plant and cinema equipment.

H J O'D Burke-Gaffney

OTRIZA, A., GONZALEZ PRENDES, M. A. & IBARRA PEREZ, R. Estado actual de la lepra en Cuba. [Present State of Leprosy in Cuba.] *Rev. Sifilografía, Leptología y Dermatología*. Marianao Cuba 1945 July Dec., v 5 No. 3 283-9

A paper read at the recent Fifth International Congress on Leprosy telling of the researches of the Society for the Prevention of Syphilis, Leprosy and Diseases of the Skin (P.S.L.E.C.) This body has established dispensaries in different parts of the island, each with its medical director who has specialized in venereal and skin diseases a medical staff nurses and laboratory technicians. The larger dispensaries have dentists also. All treatment is free and nurses visit the homes of patients, examine contacts and use persuasion to get them to attend at the dispensary. If patients cease to attend, notice is sent to them and, if that is not enough they are visited personally. The School Hygiene Department reports through the Minister of Education to the P.S.L.E.C. any children suspected of leprosy.

In Cuba, with a population of 4,778,583, there are 3,001 leprosy patients (62.8 per 100,000) of whom 2,358 are ambulatory (79.5 per cent.) and 643 are in hospital. 878 are in Oriente Province, 528 in Havana, 443 in Las Villas, 303 in Camagüey, 148 in Matanzas and 62 in Pinar del Río. 1,275 are males, 1,013 are females, the sex of 70 is not recorded. 1,122 are of the lepromatous type, 457 unspecified, 374 tuberculoid and 408 not known (or not recorded). As regards race, 1,618 are white, 414 are half-castes, 299 blacks, 12 yellow and 18 are not known. [See also this *Bullet.* 1946, v 43, 563, 603.]

II Harold Seed

ANGEL IBARRA D. Técnicas de coloración del *Mycobacterium leprae* [Methods of Staining *Mycobacterium leprae*] *Rev. Fontilles* Valencia 1949 Jan., v 2, No. 3 231-6.

This paper comprises four sections: 1. General staining of the organism. 2. Staining of the Lutz granules. 3. Difference of staining of living and of dead organisms. 4. Differential staining from *Mycobacterium tuberculosis*.

Nine methods are included under the first, but the one recommended is that of v. Halleberg—

I. Stock solution

Propionate of sodium (or potassium acetate)	1 gm.
Alcohol, 90 per cent.	100 cc.
Night Blue	5 gm.
Bismarck Brown	0.4 gm.

For use 10 cc. of this is mixed with 90 cc. distilled water. The stain is added to the slide, heated to boiling, allowed to cool for 5 minutes, washed with distilled water, decolorized with the following till no more stain comes away:

Nitric acid, 23 per cent.	4 cc.
Alcohol, 70 per cent.	100 cc.

Leave to dry. The bacilli appear blue on a dark background.

Under the second, staining of granules, again several methods are mentioned but all are modifications of Mucha's method except Spengler & Siebel's rapid method. Fix by heat, stain by warming for 2-3 minutes in a mixture of fuchsin 3 parts, gentian violet 2 parts, pour off and without washing add saturated picric alcohol for one minute, wash with alcohol 60 per cent, decolorize with dilute acetic acid (1 in 6) and afterwards with alcohol 60 per cent. Stain with saturated picric alcohol (or trypan blue) for one minute. On a yellow background the bacilli appear rose-red, and the granulations a dark violet almost black.

For the third, the Aoki erythrosin and methylene blue method is recommended. After fixing by heat, the slide is covered with the following for 5 minutes, the stain being used hot (at 80°C)

Erythrosin	1 gm
Picric acid	0.15 gm
Distilled water	100 cc

Place the specimen in a solution of potash (KOH 5 gm, alcohol absolute 30 gm., aq. dest. 70 cc) for one minute, then wash and stain with

Saturated alcoholic solution of methylene blue	15 gm
Distilled water	100 cc

Living organisms are coloured bright red and the dead or nearly dead are dark blue to violet

Lastly, for differentiating from *Myco tuberculosis*, Yamamoto's method is recommended. Place in hot silver nitrate, 5 per cent at 55-60° for 10 minutes and then in the following

Tannin	1 gm
Pyrogalllic acid	2 gm
Distilled water	100 cc

for 5 minutes, wash and dry

Tubercle bacilli are stained black, *Myco leprae* do not stain, but can be stained by Ziehl's method for greater certainty

H Harold Scott

MIGUEL, S & MIRÓ, J. El corazón en la lepra [The Heart in Leprosy] *Rev Fontilles* Valencia 1949, Jan, v 2, No 3, 202-26, 8 figs [20 refs]

The English summary appended to the paper is as follows —

"The authors study 38 cases of leprosy of the Colony-Sanatorium of Fontilles, examining the heart in order to know the participation of this organ in leprosy. Five pathologic cases are referred all of them myocarditis, in which one suspects the leprosy as an etiological factor"

SCHUJMAN, S. Es menos activo el aceite de chaulmoogra y sus derivados que las sulfonas en el tratamiento de la lepra? [Is Chaulmoogra Oil and its Derivatives less Active than Sulphones in the Treatment of Leprosy?] *Prensa Méd Argentina* 1948, Dec 31, v 35, No 53, 2499-2508, 14 figs [11 refs] English summary

There are physicians who cling to chaulmoogra and regard it or its derivatives as the only efficacious form of treatment in leprosy. Others, having obtained good results with promin, go to the other extreme and say that, compared with promin, chaulmoogra is useless. Others again, after trying chaulmoogra, get better results with promin.

In this short paper the author tells of his experience with each of these drugs and reproduces photographs showing the results in patients with tuberculous and nodular leprosy and with the macular form. These photographs seem to show that equally good results follow the use of either and the author concludes, after having treated 80 patients with the lepromatous form, that injection of 20-30 cc of chaulmoogra weekly for two years gives as good results as treatment with promin, but it is essential that adequate doses should be given over a sufficiently long period, secondly, still greater benefit may be obtained in some cases by a combination of both drugs, used alternately. His illustrations, both of patients and of the tissue changes brought about, would appear to confirm this, namely that the results are equally good.

H Harold Scott

CROVER MADAMAWY P. La tracheotomie y las sulfonas en la lepra [Tracheotomy and Sulphonas in Leprosy] *Rev. "Fouilles"* Valencia, 1949 Jan., v. 2, No. 3, 227-30.

Tracheotomy is not often called for in leprosy and then mostly as an emergency to prevent suffocation from laryngeal blocking. In ten years, among 500 patients with leprosy, 12 have undergone this operation, 8 women and 4 men. Of these 9 have died, 1 within 48 hours it was thought from some intercurrent infection, 3 at the end of one year, 3 after two years, 1 at three and one at four years—the remaining 3 have a tracheal cannula. 1 five years later, 1 two years and 1 seventeen months after operation. If care were taken to keep the nostrils clear, tracheotomy would be even less often called for.

Promin is regarded by the author as almost specific for leprosy laryngitis and it should be prescribed when hoarseness is a symptom of the disease. In fact, he sums up his opinion in these words (translated): "Promin is for leprosy laryngitis what streptomycin is for tuberculous laryngitis." [No details are given as to dosage.] H. Harold Scott

HELMINTHIASIS

LAFFENTZ, M. Les parasites intestinaux au Gabon. Résultats d'une enquête dans la région de l'estuaire. [Investigation of Intestinal Parasites in the Gabon Estuary Region.] *Indo Soc. Path. East* 1948, v. 41, No. 8, 10, 538-91.

The author carried out a parasitological examination among African laborers and their families in an equatorial forest area in the estuary of the Gabon, 50 kilometres SE. of Libreville. A specimen of faeces was examined on slide by the direct method, without concentration.

Of 525 persons, 452 (86 per cent.) were found to be infected. The parasites found were *Ascaris* (290), Hookworms (243), *Trichuris* (174), pathogenic amoebic cysts (11), *Strongyloides* (5) and *Trichomonas* (3). The infection was multiple in half the cases, including a treble infection in 36.

The author is convinced that much mortality and morbidity among children and infants can be ascribed to parasitic infections. L. E. Nafar

SANDOWAN, A. A. Some Parasitological Facts of Significance to the Clinician in Malaya. *Proc. Alim. & A. Soc. F. M. S. Ed.* 111 College / Med. Singapore 1948, Oct., v. 1, No. 1, 45-5.

General observations without references.

FERRERA, I. S. C. As parasitoses intestinais na Guiné Portuguesa. (Human) Intestinal Parasitosis in Portuguese Guinea. *Gaz. 3122* Portuguese 1949 v. 2, No. 1, 148-5.

Among 2,440 persons presenting themselves for treatment at the Institut of Tropical Medicine in Portuguese Guinea, 908 had faecal examinations made direct or by the Willis-Tekmann-Lima or Faust method. Two hundred and ninety-four (48 per cent.) contained parasites of one kind or another, 251 had single infections, 224 worms only, 22 protozoa only and 43 had multiple infection. Of the helminthic infections, hookworm (176, 79.5 per cent.) was the most common, with *Isospora* *serenata* 23 (11), next *Isospora* and *Trichuris*; cases were few only 6 each *Enterobius* 5 and *Isospora* 4, *Isospora* 4.

Of the 27 protozoal cases, 23 were *Entamoeba coli*, 2 were *E. histolytica* and 2, *Giardia intestinalis*. Taking all into consideration, single and mixed, helminthic and protozoal, ankylostomes were found in 63.2 per cent, *E. coli* in 12.9, *T. saginata* in 7.9, *Trichuris trichiura*, 4.1, *E. histolytica*, 3.5, *Ascaris lumbricoides*, 2, the others in very small numbers only.

The symptoms are mentioned and consisted mainly of abdominal discomfort, diarrhoea and, in dysenteric patients, tenesmus, but many had no subjective complaints at all and the infection was found by chance when the faeces were examined.

SHOUSHA, A. T. **Schistosomiasis (Bilharziasis) a World Problem** *Bull. World Health Organization* Geneva 1949, Mar., v. 2, No. 1, 19-30 [17 refs.]

Sir Aly Tewfik Shousha divides his paper into several sections, dealing respectively with the history of schistosomiasis, life cycle of the parasites, distribution and importance of the disease, treatment and prevention in Egypt. The three first sections are very brief, and the section on treatment refers mainly to the use of tartar emetic (the potassium salt) in Egypt. Here he shows that whereas in 1925 the surgical complications of schistosomiasis were relatively common (50.7 per 10,000), they were much more rare (2 per 10,000) in 1933, this reduction is ascribed to the effect of drug treatment on a large scale. Both *S. haematobium* and *S. mansoni* infections are involved.

The author estimates that in Egypt some 10,000,000 people suffer from these infections, and he notes that the unpleasant effects of tartar emetic are such that many patients prefer the chronic disease to the treatment, and therefore refuse to accept or finish it. "It is hopeless to try to eradicate the disease by treatment," partly because reinfection is almost inevitable. "Control of the disease by prevention of pollution and by propaganda is equally hopeless." Control by eradication of snails is possible in Egypt, where the water system of the whole country is more amenable to supervision than in most other regions. The means in use include clearance of vegetation from canals, drains and ponds, drying (which is not effective as the snails survive the 40 days of winter closure of canals), canal alternation, underground irrigation or drainage (very expensive), the use of poisons (copper sulphate is most commonly used) and of traps.

Charles Wilcocks

PIPKIN, A. C. & RIZK, E. **Vesical Schistosomiasis in the Middle East with a Report of Two New Foci in Northern Syria** *Amer. J. Hyg.* 1949, May, v. 49, No. 3, 276-84, 1 fig. [11 refs.]

After a study of the limited literature on the prevalence of schistosomiasis in Syria, schistosomiasis surveys were undertaken of the Northern and North-Eastern parts of the country. Two foci of endemicity of *Schistosoma haematobium* were disclosed: these were some 150 miles apart and sited on tributaries of the upper Euphrates river on the Turkish border of Northern Syria. In one of these (Koubour El Bid) 337 of 545 persons of all ages and both sexes examined in 19 villages were found, on a single examination, to be passing viable eggs of the worm in the urine. This high infestation rate (61.8 ± 2.2 per cent) is comparable to that among the Egyptian fellahs and for the lower Euphrates-Tigris focus in Mesopotamia, and higher than that recorded for the Palestinian focus. In spite of this high figure reasons are advanced for considering the disease to be localized to the area. While shells of a *Bulinus* sp. (probably *truncatus*) were found, no snails infected with the human schistosomes were recovered. In the other area surveyed (Tel-Abiad) persons from only five villages were examined, but nearly 100 per cent of the males and 60 per cent

of females were found infected. In view of the nomadic habits of the local Bedouins in this second area, further extension of the infection is likely to take place in this locality.

WATSON J. M. & ALI AL HAMAMI. Studies on Bilharziasis in Iraq. Part II. Incidence in the City of Baghdad. An Analysis of over a Thousand Random Urine Samples with reference to Age and Locality. *J. Faculty of Med., Baghdad Iraq* 1949 Jan. v 13 No. 1 49-62, 1 plan. [11 refs.]

Schistosoma haematobium infection has long been endemic in Baghdad, but the exact incidence has not hitherto been systematically investigated. The authors took specimens of urine at random from out patients attending the Endemic Diseases Department of the Royal Hospital. Very few of their subjects were at the hospital directly because of this infection and they make the point that as in other places where it is endemic the early symptoms (haematuria and pain on micturition) are not regarded seriously by the patients. In all they examined 887 males and 491 females the incidence rates being 7 and 14 per cent, respectively. Incidence varied from 15 to 22 per cent, in the decades up to age 50 at ages over 50 it was only 4 per cent.

The authors discuss these findings, emphasizing the fact that little or no immunity is conferred by the infection and that in Baghdad it is by no means a disease chiefly affecting children. Males are more commonly affected than females because they work in infested irrigation water and bathe in it whereas women are chiefly exposed when washing clothes and the disturbance they create in the water even if soap is not used, is surely a deterrent to the cercariae.

There was little difference in the distribution of infection in people living on the east bank of the river compared with those of the west bank, and the incidence in the different zones was fairly constant. *Bilharzia* has previously been found in canals in the city and it was known that many of the patients examined had never been outside Baghdad it appears certain, therefore that the disease is transmitted in the city.

Charles H. Deeks

GELFAND M. & ROSS W. F. The Incidence of Schistosomiasis in South Central Africa. *Trans Roy Soc Trop Med & Hyg* 1949 May v 42, No. 6, 559-64.

The incidence of schistosomiasis in sundry parts of Africa has been determined by various workers on the basis of microscopical examination of stools and urine. This method is open to criticism, especially if only one or very few specimens are examined from each person. The collection of rectal and bladder biopsy specimen is impracticable for survey purposes and the technique though good, is not an infallible diagnostic procedure. Similarly the collection of material from the rectum by digital scraping, or by a W. Her scraper is unsuitable for large-scale investigation.

Routine digestion, in 10 per cent. potassium hydroxide for 4 hours at 37°C of the entire rectum and bladder of all patient coming to autopsy and examination of the deposit for schistosome ova affords the most accurate means of determining the infestation rates within the urinary and rectal schistosomes in population. Disadvantages are the time that must lapse before sufficient large series of cases can be accumulated, the need for trained staff and special facilities, and the doubt that remains as to the degree of activity of the infection when disclosed by this means. Organs from 115 male and 35 female Africans from Northern and Southern Rhodesia from Nyasaland and from Ioropoese

East and Portuguese West Africa, were examined in this manner, from 147 (98 per cent) of these 150 cases schistosome ova were recovered. There is thus a high incidence of schistosomiasis in this wide area of South Central Africa, and the infestation rate revealed by this technique is far in excess of those previously published but based on the examination of the living. As a negative finding does not warrant the assumption that infestation is absent, it is probable that every African from this part of Africa has or has had schistosomiasis. One hundred and forty-six (99.3 per cent) of these 147 infected persons harboured *S. haematobium*, 72 (48.9 per cent) *S. mansoni*, and 71 (48.3 per cent.) both parasites. In only one single case was a pure *S. mansoni* infestation identified. *S. haematobium* ova were recovered from the bladder at 134, and from the rectum at 112 autopsies, from the bladder but not from the rectum in 22 cases, and from the rectum but not the bladder in 8. *S. mansoni* ova were recovered from the rectum at 67 autopsies, from the rectum and bladder at 5, from the rectum but not the bladder at 62, and from the bladder but not the rectum at 3.

Examination of small snips from the rectal and from the bladder mucosae showed the presence of ova in 117 of the 134 proven cases of bladder infestation (86 per cent), and 107 of the 137 proven cases of rectal infestation (78 per cent). Ninety-two cases of 134 (68.6 per cent) with bladder snips containing *S. haematobium* ova also had these ova in rectal snips. A R D Adams

MEIRA, J. A. *Schistosomiasis mansoni: a Survey of its Distribution in Brazil*. Bull. World Health Organization, Geneva, 1949, Mar., v. 2, No. 1, 31-7, 1 fig (map) [14 refs]

This paper includes a useful map which shows that infection with *Schistosoma mansoni* is very common along the coast of Brazil from the Ceará province in the north to Rio Grande do Sul in the south. Foci are also found well inland, especially in the provinces of Pernambuco, Bahia and Minas Gerais. A list of infected localities is also given: there are 364 such localities, and there are probably nearly 3 million persons (in a population of 45 millions) suffering from the infection. Charles Wilcocks

TIDY, H. *Ayerza's Disease, Silicosis, and Pulmonary Bilharziasis*. Brit. Med. J. 1949, June 4, 977-8 [11 refs] [Summary appears also in Bulletin of Hygiene]

In Ayerza's disease in Brazil, as first fully described in a monograph by ARRILLAGA of Buenos Aires in 1913, the predominant pathological change is sclerosis of the pulmonary artery and its branches, with the associated lung changes. Arrillaga's subjects were adults, and clinically cyanosis was an outstanding feature of the syndrome. Since Arrillaga's publication small numbers of isolated cases of Ayerza's disease have been recorded from all parts of the world, these have been of all ages and in few of them was the aetiology clear.

In 1928, SOROUR (C. R. Congr. Int. Méd. Trop. Hyg. Cairo, 1932, v. 4, 321) gave a fresh account of the pathology, and AZMI and EFFAT of the clinical picture [this Bulletin, 1932, v. 29, 411], of cases of Ayerza's syndrome diagnosed in Egypt. Others in Egypt have since studied the clinical picture and pathology of the condition as seen there, and it is now possible to diagnose it in its early stages, and it is increasingly being detected. The initial lesion in Egypt is an obliterative endarteritis of the small branches of the pulmonary artery, due to schistosome ova [spp. not stated] reaching the region embolically; this, with reinfection, extends to the main branches of the artery which may become aneurysmal and cor pulmonale develops, the lung parenchyma remains

uninvolved. While the hypertrophied right ventricle succeeds in forcing sufficient blood through the obstruction there is no cyanosis when it fails to do so cyanosis appears. The Egyptian cases differ from the Brazilian in that cyanosis is not marked in the former and the pulmonary symptoms are mild.

There are thus two distinct regions where pulmonary arterial sclerosis is known to be relatively common, Brazil and Egypt. In Brazil gold mining at an altitude of 14 000 feet is the local industry—silicosis may be the primary aetiological factor and the great altitude may cause the severe cyanosis characteristic of the condition in this area. Removal to a lower altitude has been shown to diminish the cyanosis in these cases. Pulmonary bilharziasis does not seem to have been reported from Brazil, where *Bilharzia mansoni* is the prevalent schistosome. In Egypt schistosomiasis is the primary aetiological factor and cyanosis is not a feature of the syndrome until terminally when the heart fails. Nevertheless, in Brazil also the possibility of pulmonary schistosomiasis as a main or contributory factor in Ayerza's disease should be borne in mind.

BLAIR, D. M., HAWKING, F., MEYER, C. V. & ROSS, W. F. Miracil. Clinical Trial on Patients Infected with *Schistosoma haematolum* and *S. mansoni*. *Brit. J. Pharmacol. & Chemotherapy* 1949 Mar. v. 4 No. 1 68-70 [13 refs.]

The thioxanthone Miracil D synthesised in Germany was found by JUKKE & GÖNERT (this Bulletin 1949 v. 46 481) to be active against experimental infections with *S. mansoni* in mice and monkeys. WARSON *et al.* used the drug in treatment of schistosome infections in Egypt (ibid. 1949 v. 45 1018) and BLAIR *et al.* have given a preliminary report of their findings in *S. Rhodesi* (ibid., 1949 v. 45 529). The drug is best given by mouth as subcutaneous or intramuscular infection causes irritation. Most patients in the present trials were young Africans with active infections. After clinical examination, the drug was administered usually as 100 mgm. tablets by mouth and at intervals examinations of urine or faeces were made for eggs or miracidia. In one series 44 young persons, some with double infections of *S. haematolum* and *S. mansoni* were treated with daily doses of 0.1 to 0.7 gm. of Miracil D on 6 days per week over a period of 3 weeks. The follow-up was made at weekly intervals over a period of 16 weeks or longer. After 1 week, 11 patients with *S. haematolum* infection and 1 with *S. mansoni* appeared to have been cured. The infections in these cases were originally light and those with double infection were sometimes freed from one species of parasite only. In a second series of 13 boy patients the dose of drug was increased to 0.6 gm. daily and was given on 17 occasions. The total dose was 35 to 150 mgm. per kid. After 4 months four of them appeared to be cured. When 18 boys 1 to 14 years infected with *S. haematolum* were given doses 1.0 to 0.7 gm. of Miracil D daily over a period of 10 days 12 of their number were not passed in all eggs at the end of 15 weeks. Some of 11 patients in hospital were given much as 1.8 gm. daily for a period of 8 days. Results in these cases were favourable.

The description of treatment which is given in great detail (1 tab.) will be consulted in the original by those interested. Treatment led not to haemoglobin levels or white cell numbers of the blood and there were no changes in urine. Only one European (included in the first series) showed yellow colouration of the skin and conjunctivae. Anorexia, low blood sugar and vomiting occurred in some groups of patients. In one a pruritic and a herpesiform rash occurred possibly due to schistosome death. No serious toxic manifestations were noted. The drug did not accumulate in the

body, and was estimated in blood by the method of LATNER *et al* [this *Bulletin*, 1948, v 45, 96]

As supplies were limited, only one African patient in each instance was treated with Miracil A, B and C respectively, the total dosage being 1.5 to 1.8 gm in a period of two weeks. These substances are xanthenes in which the sulphur atom of Miracil D has been replaced by oxygen, together with other minor changes in the molecule. No cures were obtained. Evidence has been obtained that a large proportion of patients harbouring *S. haematobium* can be sterilized of this infection by safe doses of Miracil D, but *S. mansoni* responds less well to treatment. The intensity of dosage appears to modify the results obtained and further investigation is indicated, particularly in order to define more accurately the maximum tolerated dose, whether dangerous idiosyncrasies exist and how the therapeutic effect of large doses compares with that of antimonials.

ZIEVE, L & CONLEY, R H. Chronic Schistosomiasis Japonica diagnosed by Rectal Biopsy. Report of Case. *Minnesota Med* 1948, Dec, v 31, 1331

OLIVIER, L. The Penetration of Dermatitis-producing Schistosome Cercariae. *Amer J Hyg* 1949, Mar, v 49, No 2, 134-9

"Observations were made on the penetration of human skin by cercariae of *Trichobilharzia stagnicolae*, the chief cause of schistosome dermatitis in the United States. It was found that the cercariae will penetrate while fully submerged and, therefore, do not require an evaporating film of water to stimulate or aid penetration. In some tests the cercariae penetrated from relatively cool water (17°C to 23.5°C), the temperature of which changed little during the exposure period. It was also found that the itching associated with penetration of the cercariae occurs very soon after the cercarial body enters the outermost layer of the skin and that, therefore, this primary itching may be taken as a reliable indicator of the time of penetration of the cercariae. Primary itching was found to begin from 4 to 10 or more minutes after the cercariae were placed on the skin, indicating that the cercariae remain on the surface of the skin for some time before penetrating."

OLIVIER, L. Schistosome Dermatitis, a Sensitization Phenomenon. *Amer J Hyg* 1949, May, v 49, No 3, 290-302, 2 figs [15 refs]

In 1928 CORT [this *Bulletin*, 1928, v 25, 946] showed "swimmers' itch" in Michigan, U.S.A., to be due to non-human schistosome cercariae. MACFARLANE [*ibid*, 1944, v 41, 947] identified a non-human schistosome cercaria causing a similar condition in New Zealand, and suggested that sensitization resulted from repeated exposure to it. The matter was deemed worthy of further study. Cercariae of *Trichobilharzia stagnicolae* from the snail *Stagnicola emarginata angulata*, of *Trichobilharzia ocellata* from *Lymnaea stagnalis*, and of *Schistosomatium douilii* from *Stagnicola palustris* were applied to the forearms of volunteers at the N I H laboratory, Bethesda, and at the University Biological Station, Michigan. Typical schistosomal dermatitis was produced in susceptible persons by any of these, and the lesions produced were undifferentiable.

Of 34 persons exposed for the first time (as far as could be ascertained) to cercariae of *Trichobilharzia stagnicolae* all but one suffered only a mild reaction with inconspicuous lesions. The odd case had a more severe reaction, and investigation of his history suggested he might have been exposed to *Schistosoma mansoni* cercariae in Porto Rico previously. Twenty-seven volunteers were then exposed to from 2 to 8 further attacks by the same

cercariae at irregular intervals (a few days to about 120 days) and increasing reactions culminating in some cases in typical schistosome dermatitis developed in 21 of them. In some of these persons on re-exposure to infection reactivation of earlier lesions was observed. The reactions were not a local phenomenon as changes in the site of application of the cercariae still produced them—they were essentially allergic in nature and there is evidence that a sensitization once acquired may persist for some years. *A. R. D. Adams*

KENDALL, S. B. *Limnaea stagnalis* as an Intermediate Host of *Fasciola hepatica* [Correspondence] *Nature* 1949 June 4 880-81

Hitherto the possibility of British species of *Limnaea* other than *L. truncatella* acting as vectors of *Fasciola hepatica* has been open to doubt. The author now describes experiments carried out at Weybridge Veterinary Laboratory which prove that *F. hepatica* is capable of completing its development in *L. stagnalis* with the emergence of cercariae and ultimate infestation in mammals.

The snails used were freshly hatched second generation specimens reared in the laboratory under strict conditions. Massive exposure to fresh miracidia of *F. hepatica* resulted in infection occurring in 13 of 101 experimental snails from one of these 99 perfect cercariae emerged and four of these infected a rabbit orally. In six weeks a half-grown *F. hepatica* was recovered from the bile ducts.

Failures by previous workers to infect adult specimens of *L. stagnalis* are referred to and it is suggested that immature specimens are more susceptible than are adults.

The author suggests however that this observation may have little significance from the veterinary point of view because of the aquatic habit of *L. stagnalis*, which appears to be confined to permanent water. The biological significance of the finding is however stressed and is being followed up in relation to other species of *Limnaea*. *H. J. O'D. Burke-Gaffney*

FUERTES DELGADO, M. Formas autotomoclinicas de la cisticercosis cerebral [Anatomical and Clinical Forms of Cerebral Cysticercosis.] *Cac. Med. de Mexico* 1948 Aug 31 v 78 No. 3 154-73 7 figs on 6 pls

DESCHERES, R. Les substances toxiques vermifuges leur pouvoir pathogène leur identification [The Pathogenic Power of Toxic Substances in Helminths.] *Ann. Inst. Pasteur* 1948, Nov v 73 No. 5 397-410 5 figs. [22 refs.]

The following is a free translation from the French of the author's summary.

Pathogenic products of helminthic origin can be divided into two groups according to the nature of their effects. 1. Polypeptide toxic substances. 2. Protein globopied and polysaccharide (sic ² polysaccharide) substances having allergic and anaphylactic properties. Those of the second group are eosinophilogenous—those of the first group are not.

The pathogenic action of toxic helminthic substances can be demonstrated experimentally in guinea-pig, cat and rabbit either by acute or chronic intoxication—the disease caused by this experimental method resembles that occurring under natural conditions.

Acute and chronic intoxication due to toxic helminthic substances produces biological reactions and a symptomatology comparable with those of acute or chronic histamine intoxication.

The pathological anatomy of lesions due to chronic helminthic intoxication consists of inflammatory oedematous infiltration and necroses which are selective in lungs, kidneys and liver. A plastic helminthic anaemia is also often observed.

The toxic helminthic substances belonging to the polypeptide group are not identifiable with histamine, but they can be assumed legitimately to be basically amine or amino-acid and related to, or capable of liberating or forming, histamine in the organism.

Helminthic substances having allergic or anaphylactic properties are distinct from toxic helminthic substances, they seem to resemble in particular protein fractions properly speaking, gluco-proteins and polyholsides.

From the practical aspect, bearing in mind that fundamentally the treatment of helminthiasis belongs to the sphere of chemotherapy and galenotherapy, a knowledge of toxic helminthic substances is concerned not merely with the interpretation of certain parasitic diseases, but also with the possibility of arriving at antitoxic and symptomatic treatment in acute conditions.

J J C Buckley

DESCHIENS, R & POIRIER, M. Anatomie pathologique de l'intoxication expérimentale subaiguë et chronique par les substances toxiques vermineuses [Pathology of Subacute and Chronic Intoxication in Experimental Animals by Toxic Helminth Extracts] *Bull Soc Path Exot* 1949, v 42, Nos 1/2, 70-75, 4 figs on 2 pls

The authors' experiments with laboratory animals on the effects of injecting extracts of *Ascaris megaloccephala*, *Taenia saginata* and hydatid fluid show that both in regard to the localization and the nature of the lesions produced, the three substances have a homogeneous character. The respiratory organs, the liver and kidneys are always affected in degrees which vary with the nature of the substance and dosage employed. The *Taenia* extract produces signs of congestion, irritation and oedema and rarely, degeneration. The hydatid fluid is more toxic and gives rise to inflammation, not infrequently with degeneration and necrosis and also haemorrhage. The *Ascaris* extract is particularly toxic and produces inflammation, degeneration and haemorrhage. Although anaemia is not always present, hyper-leucocytosis, usually without eosinophilia, is a constant feature of the toxic effects. The lesions exhibit a marked analogy with those produced in guinea-pigs by administration of histamine.

NEWTON, W L, BENNETT, H J & FIGGAT, W B. Observations on the Effects of various Sewage Treatment Processes upon Eggs of *Taenia saginata* *Amer J Hyg* 1949, Mar, v 49, No 2, 166-75 [12 refs]

"Experiments were set up for the evaluation of the effects of various sewage treatment processes upon eggs of *Taenia saginata*. The results and observations obtained before the limited supply of material was exhausted are presented.

"Twenty experiments were performed to observe the settling characteristics of *T. saginata* eggs in an 18-inch column of raw sewage. The settling rates obtained were as follows: 65 per cent of the eggs, 0.6 inch per minute or faster; 16 per cent, 0.3 to 0.6 inch per minute; and 17 per cent, 0.15 to 0.3 inch per minute. These results indicate that sedimentation of raw sewage with moderate overflow rates and for 1-to-2-hour detention periods would remove the majority of the eggs. However, even under optimal conditions a significant percentage of influent eggs would escape the effluent.

"Seven experiments were conducted with the sand filtration process. A 12-inch column of sand, 0.5-millimeter effective size, was used. The filtration

rate was 1 000 000 gallons per acre per day and effluents contained 50,000 to 200 000 *T. saginata* eggs. The failure to recover eggs in the effluents, with one exception (0.4 per cent recovery) at this extreme of operational conditions indicates that the process would be a very effective method of checking the spread of *T. saginata* eggs in primary effluent.

"On the basis of the results obtained from two digesting sludge experiments still in progress it would appear that this process is very slow in destroying *T. saginata* eggs. While there has been an obvious deterioration of many of the eggs, apparently normal eggs have been recovered from sludge after 6 months of digestion at 75° to 85° F.

Two experiments were performed with a laboratory-model trickling filter operated at rather slow rates. Recoveries of 30 and 38 per cent of infective eggs suggested that this process would not provide adequate protection against an effluent contaminated with *T. saginata* eggs.

One experiment with the activated sludge process still in progress indicates that this process would have little effect upon *T. saginata* eggs. After 5 months of aeration there has been no noticeable effect upon the eggs as determined by microscopic examination.

"The results of these experiments indicate that, if sewage were contaminated with *T. saginata* eggs, the usual treatment processes (with the exception of sand filtration) could not be relied upon to produce effluent or sludge free of viable eggs.

NEGUETE R. A. FAIGUENBAUM A. J., PILOTTI A. M. & SILVA CANTOS P.
Algunos aspectos epidemiológicos de la hidatidosis humana en Chile
[Some Epidemiological Features of Hydatid Disease in Man in Chile] *Rev. Chilena de Hg. y Med. Preventiva* 1949 Dec. v 10 No. 4 197-207

This study is based on the records of the 17 years 1933-1944 inclusive. Though the actual number of cases of hydatid infestation has more than doubled—from 189 in 1933 to 399 in 1944-45 (in 1941 it reached 415)—and the ratio per 100 000 inhabitants has risen from 4.68 to 7.91 (7.91 in 1947) it is not certain that the numbers have really increased to anything like this extent: diagnosis is better and more hospital beds have been available so that the numbers of patients admitted for treatment of all diseases has risen. For estimating the geographical distribution the country has been divided into five zones: north, central, south, austral and North Chile. Most cases occur in the central zone with the Provinces of Valparaíso, Santiago and Maipo. It is agricultural and largely given up to cattle-raising. As regards sex distribution male patients are slightly in excess of female but the difference is not significant. The ages of 1495 patients during the 17 years were ascertained and 1407 (48.9 per cent) were in the 20-39 year group and 71 (23.7 per cent) in the 40-59 year group but there were 616 (20.7) in the second decade. The fatality rate has remained fairly stationary except for a rise in 1941. The reduction since that year is ascribed partly to earlier diagnosis and partly to improved surgical technique. The chief cause of spread of infection is as usual the close connexion between dogs and cattle: some 30-78 per cent of dogs around slaughter-houses being infested with *Echinococcus granulosus*.

QUEENSLAND ANNUAL REPORT OF THE HEALTH AND MEDICAL SERVICE OF THE STATE OF QUEENSLAND FOR THE YEAR 1947-48, pp. 32-4 Hookworm Campaign THOMPSON S.

In July 1947 the field hookworm campaign in Queensland was staffed by macroscopist 3 residential sisters and field inspector. There was close co-operation with the Weil's disease staff.

A large table gives detailed figures showing the topographical distribution of laboratory examinations and treatments. It is noted that 622 of 4,787 specimens were positive for hookworm. 320 of the infected persons have been treated to a cure. In all, 756 specimens contained other parasitic worms.

In each area inspected, arrangements were made with the local medical officers for 25 children under 3 years to be treated and observed in hospital. Of 1,977 school children, 88 harboured hookworm and 252 had other helminthic infections. 40 of the hookworm hosts have been treated to a cure.

Practical measures included spreading of lime on infected soil in the aboriginal reserve, inspection of sanitation at the homes of infected persons and close co-operation with medical, health, educational and mission authorities.

[References to co-operation with the staff of another campaign show evidence of an admirable spirit but it is often to be asked, when health campaigns are undertaken in large and remote areas, whether multiplication of *ad hoc* survey or treatment teams is to be preferred to health teams with a broader mandate, equipped to deal with any of the local health problems as they are encountered.]

FLOCH, H & CAMAIN, R. Sur un nouveau cas de pseudo myiase rampante à *Ancylostoma brasiliense* en Guyane française [A New Case of Creeping Eruption due to *Ancylostoma brasiliense* in French Guiana] *Bull Soc Path Exot* 1949, v 42, Nos 1/2, 29-33, 5 figs

Observations were made upon a creeping eruption which appeared on the thigh of a male child of 3 months in French Guiana. The condition first appeared as a thread-like ridge which grew to about 1 centimetre long in two days. During the period, 25th July, 1947, to 30th August, 1947, the course of the track, which is illustrated by a drawing, was observed. Biopsy was then performed under a local anaesthetic, on the terminal part of the track, after which the condition cleared up and did not recur. Serial sections (15 μ thick) of the excised piece of skin revealed a nematode 650 μ long by about 20 μ in width, in the dermis lying parallel to the skin surface. Reaction in the neighbourhood of the worm included dermal necrosis and cellular infiltration with monocytes and lymphocytes, but no eosinophilia was noted.

The parasite is armed at the anterior extremity with a strong pair of curved teeth, 4 μ long by 3.5 μ diameter at the base. 9 μ posterior to these are two folds meeting in the middle line, which apparently represent a buccal capsule. Then follows an alimentary canal of 4 μ to 6 μ in width. On morphological grounds the parasite is tentatively identified as *A. brasiliense*.

DE OLIVEIRA, P. P. Strongiloidose, problema sanitário. Incidência numa coletividade militar (1° GAC Motorizado) [Infestation by *Strongyloides stercoralis* a Sanitary Problem] *Hospital* Rio de Janeiro 1949, Mar, v 35, No 3, 437-43, 5 figs

The author, an Army Medical Officer, examined the faeces of 299 recruits in the Province of Espírito Santo, using Baermann's method, and found the larvae of *Strongyloides stercoralis* in 82 of them (27.4 per cent).

This helminth causes considerable disturbance—colic and diarrhoea, asthmatic attacks as the larvae pass through the lungs, blood changes of haemolysis, leucocytosis and eosinophilia. Considering that so many individuals who should be in good health, as recruits, harbour this parasite, the question is clearly one not only of medical but of public health concern.

The author claims that elephantiasis of the legs of streptococcal origin is rapidly cured by intramuscular injections of Rubiazol (a sulphonamide preparation) on three days a week and intravenous injections at similar intervals of solution composed of —

Sodium thiosulphate 0.4 gm.
Magnesium thiosulphate 0.1 gm.
Distilled water 5 cc.

The latter method has been commercialized under the title of desensitizing injection and is thought to reinforce the action of Rubiazol: this form of therapy can be supplemented by intravenous injections of iron and calcium gluconate.

The reduction of the swelling is aided by means of compression by an elastic bandage which clears away the oedema. This paper is illustrated by three photographs depicting the one case described. (The evidence is by no means convincing, as the elephantiasis is of moderate degree only and the diminution of the oedema could be attributed to compression by the elastic bandage.)

- BUCKLEY J. J. C. Studies on Human Onchocerciasis and *S. mal. m.* in Nyanza Province, Kenya. I. Distribution and Incidence of *O. viverrini*. *J. Helminthology* 1949 v 23, Nov 1/2, 1-4 2 maps & 5 graphs. [11 refs.]

This paper is the first of a series which will describe an investigation into onchocerciasis and its vector *S. mal. m.* in the Nyanza Province of Kenya. Five foci of the disease were studied: all lay in the altitude range of just below 5 000 feet to just below 6 000 feet. Onchocerciasis was absent in the low-lying plains and in the higher mountains. The five infected localities were Kodera, Ruana (a focus discovered for the first time) Kuja River, Lumbwa and North Kauroodo. Preliminary surveys were undertaken in the first four by the taking of skin snaps from members of the population. The author used the method he had devised for detecting *O. pectus* in the skin of cattle in Malaya. The skin is pinched up between the thumb and forefinger and a very

thin piece about 5 mm in diameter is sliced off with a sharp razor. The skin snip is placed in a drop of saline on a slide, is allowed to stand a few minutes, and is then examined under a low magnification ($\times 230$). The microfilariae are readily detected in the saline. No local anaesthetic is necessary and centrifugation need not be employed. The distribution of microfilariae in the skin of different parts of the body varies so enormously that quantitative estimations are useless; in one case, there were two microfilariae in a skin snip from the thigh and 393 in another piece of similar size taken only 3 cm away.

The incidence of the disease was then studied in detail, and observations were made on the ocular effects, cutaneous manifestations and abnormal skin conditions. The incidence in the population increased progressively with age, as the cumulative result of exposure to infection over a long period. Microfilariae probably first appear in the skin between the ages of 2 and 3 years; children of this age in one locality showed a 19 per cent infection rate, then from 5-7 years, 29 per cent and 8-10 years, 34 per cent. In the young adults the rates rose to 55 per cent and in the oldest age group to a maximum of nearly 80 per cent. In most localities men were more affected than women, probably because the men spend more time in surroundings infested with *Simulium*, among the Kisu tribe, however, for a reason not understood, the women suffer more than the men. The effects of the disease in some of the highly infected areas are shown below.

(Percentages)

Place	Positive Skin Snips	Eye Lesions	Nodules	Abnormal Skin
Kodera	48	9	5	15
Riana	21	2	3	15
Lumbwa	29	2	3	9
N Kavirondo	72	10	24	25

It was thought that the eye affections were probably much more common than these figures suggest; many blind people remained in their houses. It was not always possible to assess the rôle played by *O. volvulus* in the causation of these affections—particularly the eye and skin manifestations.

The foci of the disease were always associated with the presence of *Simulium neavei*, the principal species to bite man in Kenya. The ecological requirements of this insect were clearly revealed, fast-running rivers, a hilly terrain, well-wooded banks, and probably certain temperature requirements which tend to limit the species to altitudes well below 7,000 feet.

The survey embraced the examination of 5842 Africans and is the most comprehensive of any yet reported from Kenya. Details are given of the incidence in the smaller localities, in mines and elsewhere.

BURCH, T. A. Experimental Therapy of Onchocerciasis with Suramin and Hetrazan. *Bol. Oficina Sanitaria Panamericana* 1949, Mar., v 28, No 3, 233-48 [12 refs.]

At a clinic established in an area of Guatemala where onchocerciasis is endemic, 182 patients were treated; the report deals with 108 of these patients.

Fifty-six patients were treated with naphuride sodium (Suramin). In the first 12 cases they were given intravenous doses of 0.02 gramme per kilo body-weight, but the remainder were given only 0.5 gramme initially followed by 1.0 gramme weekly, for 5 to 7 weeks, a total dosage ranging from 0.31 to

0.07 gramme/kilo. Details of 48 patients are given, of which 43 showed microfilaria in skin biopsies before treatment. At the end of treatment 70 showed negative biopsies (at least four such) of which 13 were still negative at the end of 5-6 months. At the end of 7-8 months, of the 13 cases followed, 12 were negative—five of these had been positive at an earlier post treatment stage but none of them later than 1-2 months.

The reactions were annoying and discouraged at least half the patients from continuing treatment until it was complete but in none was it really necessary to discontinue—these reactions apparently due directly to the drug, were burning of the feet or palms and occasionally peeling or fissuring, muscle and joint pains, nausea, abdominal cramps, headaches, sleepiness and transitory swelling of the lips. Other reactions that were apparently due to the effect of the drug on the onchocerca were ocular reactions, pruritus, local induration, fever and "peculiar feelings" inside the onchocerca lesions.

Fifty-two patients were treated with Ihetrazan—of these 11 were given a total dosage of 20 to 46 mgm. per kilo. body weight with an initial dose of 0.5 mgm. per kilo. in 8 cases. Later an initial dose of 0.1 mgm. per kilo. was given and the dose was increased gradually—only three of the latter group received more than a total dose of 18 mgm. per kilo.

The effect of treatment was dramatic in the former group. Two patients showed no microfilariae throughout. Of the other 9 one only (20 mgm.) showed microfilariae at the end of treatment—the rest were also negative after 1 month, but microfilariae returned in two cases at 3-4 months—in one case at 5-6 months and in two more at 7-8 months so that only 3 of the original 9 microfilaria-positive cases remained free after 7-8 months, but another patient positive at 3-4 months became negative subsequently. Of the group receiving smaller doses only 7 showed no return of microfilariae but these were not followed for a sufficiently long time to make the observation important.

The side-effects with Ihetrazan were more serious. In seven cases the course of treatment was modified or stopped on account of them and many other patients refused to continue the drug. The side-effects included headache, general malaise, weakness, fainting spells and vertigo, abdominal cramps, aching pains in the joints and teeth, pruritus (in 43 cases), ocular reactions (in 22 cases), induration and oedema, papular eruption, and fever. These latter symptoms were as in the case of Suramin treatment, attributed to foreign protein from killed worms.

The results of treatment with comparable doses of Ihetrazan in *Wuchereria bancrofti* infection [SANTIAGO-STEVENSON *et al.* this *Bulletin* 1948, v 45 355] were not as good since only 1 out of 7 patients observed remained free from microfilariae after 7-8 months but with larger doses 73 to 135 mgm. 3 out of 4 were free from microfilariae after this period of observation.

MARTÍNEZ RÍVEZ, M. Consideraciones sobre el examen de los nodulos oncocercosos en la investigación de la acción macrofilaricida de algunas drogas. (Examination of *Onchocerca* Nodules in studying the Effect of Drugs on the Adult Worms.) *Rev Inst Sal. P.ública y E. Farmacéut. Trop. México* 1949 Mar 10 No. 1 17-27 8 figs.

The success of Ihetrazan in ridding the body of embryos of *O. viverrini* has been reported so often that it may now be taken as proved. As regards the action of the drug on adult worms opinion is not settled. Some of degeneration in the worms has been noted and examination of nodules reveal scarce embryos—they may be absent altogether—and those present are distorted, moribund and even dead.

In this article the author indicates how cautious we should be in interpreting these effects as due to the drug. He examined 300 nodules extirpated from supposed *Onchocerca* infections, fixing and staining the tissues in various ways. Twenty-one proved not to be *Onchocerca* nodules, but lymphatic glands, sebaceous cysts and the like, 168 (56 per cent of the total, 60 per cent of the true *Onchocerca* nodules) contained adult worms. Some [proportion not stated] appeared normal, with eggs and embryos, others were more or less degenerated, with contorted, ill-defined outline and tissues necrotic or on the way to becoming so, with musculature fragmenting, in short all the signs which have been recorded as following the administration of Hetrazan, although the patients from whom these tumours had been taken had had no treatment. Another good example of the *post ergo propter* fallacy

SANDOSHAM, A A A Case of Human Gnathostomiasis in Malaya. *J Helminthology* 1949, v 23, Nos 1/2, 71-2, 1 fig

The first record of human gnathostomiasis in Malaya was made by SAMY [this *Bulletin*, 1919, v 13, 213] the case now recorded is the second from Malaya. The worm was removed from the pulp of a finger of a Chinese woman in 1947 she had emigrated from China as a child and had lived near Ipoh for 29 years

The worm presented at the advancing end of a raised linear track extending from a septic swelling over the nail bed. It appeared as a black object under the skin and had taken five days to travel from the dorsum of the finger to the pulp. Removal of the worm was followed by rapid healing. Morphological details of the worm are given and illustrated with line diagrams

The author refers to previous records from Asia [this *Bulletin*, 1934, v 31, 801, 1936, v 33, 136, 1945, v 42, 919] Some of the Chinese in Malaya are given to eating raw freshwater fish and human gnathostomiasis may be commoner than has been suspected

It was not possible to determine the species with certainty, but it is suggested that the specimen was a larval form of *Gnathostoma spinigerum*, which (with *G. hispidum*) has been recorded from domestic animals in Malaya

EBERT, Carla Oxyuren-Nachweis mittels Cellophanklebestreifen [Demonstration of *Enterobius* by the "Cellophane" Method] *Med Klin* 1949, Mar 25, v 44, No 12, 375, 1 fig

The author has modified the older method of making a smear preparation from "Cellophane" anal swab for recognition of *Enterobius* eggs. She attaches an adhesive "Cellophane" strip some 6 cm long and 1.5 cm. broad in the anal cleft, presses it against the anus and leaves it overnight. The female worms come out, deposit their eggs and, in the morning when a smear is made on a slide, ova in large quantity and the worms themselves may be seen by low magnification. Of 250 children between the ages of 2 and 14 years examined thus, 217 (87 per cent) were positive, whereas by the older smear method only 120 (48 per cent) were positive. Another advantage is that the procedure can be carried out in the home by the mother and preparations can be kept for a week if necessary before being examined

KETELSLEGERS, J L'appendicite vermineuse par oxyures [Appendicitis from *Enterobius* Infestation] *Rev Belge Sci Méd* 1946, Oct, v 17, No 5, 295-314, 7 figs on 2 pls [45 refs]

In 1901, Metchnikoff first drew attention to the association between worm infections and appendicitis. Since this date there have been many reports

confirming this association the worms usually incriminated are *Axaru lumbricoides*, *Trichuris trichiura* and *Enterobius vermicularis*.

In 23 appendices of children, eggs of one or more of these worms were found in 12 instances, and in 11 appendices of adults in 5 instances. *Enterobius* with or without other worms was present in 8 children and 2 adults.

A number of clinical histories are given together with pathological details of the removed appendices.

The conclusions at which the author arrives are—that *Enterobius* undoubtedly plays an important rôle in the pathology of chronic and subacute appendicitis, and that in acute appendicitis it favours the action of the bacteria, especially in children—that these worms invade the mucous membrane causing erosions and ulcers, and enter Lieberkühn's glands and lymph follicles, disturbing the entire structure of the tissues and causing hæmorrhages of varying degrees in the tissues invaded, and that, even in the absence of lesions, they leave traces of their presence in the tissues—that although the clinical diagnosis did not always correspond with the histological, on the whole the histological picture presented in the cases of acute and subacute appendicitis were distension of Lieberkühn's gland with mucus, hyperplasia and often an increase in lymph follicles and simple hyperplasia of lymph glands—and that in all cases where *Enterobius* was present there was distinct hypereosinophilia, especially in the areas of hæmorrhagic infiltration.

L. E. Napier

SCHÖFFNER, W. Kritische Betrachtung der Oxyuriasis-Therapie und Vorschläge für die praktische Ausführung [Critical Inquiry into the Treatment of *Enterobius* Infestation and Hints on Practice.] *Med. Klin.* 1949 Mar 19 v 44 No. 11 334-8. [15 refs.]

It is obvious that a cure of *Enterobius* infestation can be claimed only if the worms are cleared out and do not return, excluding of course re-infestation. The author has shown by human experiment that development may be slower than is generally thought viz. 14-35 days according to Heller to 60 days according to Faust—he found that as long as 83 days might lapse between ingestion of ova and appearance of fresh ova in the faeces from the developing worms—the shortest interval was 37 days. Distinction is made between re-infection (or fresh infection) and retrograde infection or retrofection in which the larva develops after the egg is extruded and then crawls back into the anus and develops in the ordinary way. Early worms, i.e. those seen in the first 37 days, may be either such as are resistant to the drug used (or the drug was given in too small a dose) or the drug, having acted on the adult gravid (females) has no action on the younger immature forms and these develop normally or thirdly they may have hidden themselves in the appendix or in some spot where the drug has not reached them.

It has been said that 10-14 days after the treatment there should be an examination for ova and if they are found the course should be repeated. The author does not agree with this. One should bear in mind what he has stated above—that development of the worm may be slow and eggs passed later than the 14 days. Also ova from worms which had hidden in the appendix might appear later and would be no proof that the drug was ineffectual, as it would have acted only on those worms which were accessible to it. Daily search for ova is necessary for gauging the results of treatment, and only when there are definite indications that the course has failed should it be repeated or another drug be tried. Quoting from the literature the author mentions several drugs which have been recommended—oil of chenopodium, gentian violet, crystal violet, phenothiazine and others. Preventive measures must vary according to the method of infection, whether this be digital transference

indirect contact by eggs on food, retrofection and dust infection, but all such measures may be summed up in cleanly habits, washing of hands and "anal toilet"

NEGhme, A Present Status of Trichinosis in Santiago, Chile *J Parasitology* 1949, Apr, v 35, No 2, 136-7

Between 1938-48 small familial epidemics of trichinosis have occurred in the province of Santiago, Chile, where some 50 human cases occur annually. In 1944, autopsy of diaphragm muscle from 296 persons dying in Santiago hospital revealed the presence of trichinae in 12.5 per cent. Although the disease is endemic in Chile, it is mostly benign and mortality in recognized cases is very low. The author illustrates this by reference to an outbreak described by him and his collaborators from a Military School in Santiago in 1947 [this *Bulletin*, 1948, v 45, 356].

In the same year, 157 acute cases of trichinosis were found in Santiago between July and October—a month before the epidemic began, many hogs had been slaughtered and a transient shortage of beef at that time had led to an increased consumption of pork.

Surveys in the municipal slaughterhouse revealed an incidence of trichinae among hogs of 0.2 to 0.3 per cent, the highest being in animals raised in garbage lots. Microscopic inspection of slaughtered hogs for trichinae is compulsory in Chile, but a survey of 52 slaughterhouses in Santiago province suggest that this was being done as a routine measure in only five establishments.

New regulations were introduced in 1947, whereby hogs shall be slaughtered only in slaughterhouses where microscopic examinations for trichinae are carried out as a routine—eight specimens of muscle from each hog must be examined—the raising of hogs in garbage lots and feeding them with uncooked garbage are prohibited. In connexion with this, it was found that 5 per cent of 822 hogs in one garbage lot harboured the parasite, as did 8 per cent of 200 rats trapped on the same premises.

While the author agrees with GOULD [this *Bulletin*, 1946, v 43, 578] that processing pork is the most effective method of controlling trichinosis, such measures are not feasible in Santiago at present. Reliance must therefore be placed on the new regulations and on education of the public. It is added that microscopical inspection, especially with the phototrichinoscope, has not proved to be so expensive in Chile as it has been reported to be in other countries.

H J O'D Burke-Gaffney

NEGhme R, A, HOECKER S, G & FELNER P, Eva Incidencia de Triquinosis en las ratas de basural y su posible relación con el grado de infestación de los cerdos criados en el mismo sitio [Incidence of Trichinosis in Rats from Garbage and its possible relationship to Pigs reared in the same Place.] *Rev Chilena de Hig y Med Preventiva* 1948, Dec, v 10, No 4, 209-12

The English summary appended to the paper is as follows —

"The authors have examined 200 rats trapped in a garbage-lot of Santiago, Chile, and found 8% infected with *Trichinella spiralis*.

"They discuss the relationship between this finding and the high incidence of Trichinosis (5.1%) found in 822 hogs reared in the same place."

DEFICIENCY DISEASES

WOOD I. J., GARLICK, H. W., MOTTERAM R., WEIDEN S., MOORE, A., MACKAY M. & TURNER, C. V. Nutritional Disease of the Liver. *Med J Australia*, 1949 Apr 23 v 1 No 17 541 7 1 fig. [25 refs.]

The occurrence of fatty infiltration of the liver and its development through periportal fibrosis to Laennec cirrhosis as a result of malnutrition, particularly protein deficiency has been frequently described in recent years. The studies of early cases have been made largely in children and the end results in adults have been increasingly recognized.

The authors describe the development of nutritional disease of the liver in eighteen adult patients. The commonest cause of the malnutrition was chronic alcoholism, but in a minority of cases the causes included other organic diseases, dietetic obsessions, poverty or a solitary existence. The later results of the condition have been long known, but attributed primarily to alcoholism; the importance of malnutrition as the main causative factor has been insufficiently recognized. The cases were studied clinically and biochemically, and material for histological study was obtained by aspiration biopsy of the liver.

The main clinical manifestations of nutritional liver disease were limited: mental depression, muscular weakness, and failure of memory and concentration, with anorexia, nausea and morning vomiting. Jaundice was occasionally seen and haematemesis was not uncommon, especially in the advanced cases. The liver was usually enlarged, and vascular changes included dilatation of superficial veins, blood-shot eyes and occasional scattered spider naevi. Associated manifestations of vitamin deficiency included peripheral purpura, petechial haemorrhages, atrophy of the tongue and angular stomatitis. A reliable dietetic history was difficult to obtain from the alcoholic patients, but persevering inquiry revealed the true aetiology of the condition.

Biochemical investigations showed that liver function tests (serum bilirubin, cephalin flocculation, hippuric acid excretion, urine urobilinogen alkaline phosphatase) give results within normal limits in early cases but are a reliable guide to prognosis in more advanced cases. [The bromsulphthalein clearance test regarded by some workers as the most sensitive liver function test in this type of condition (WATERLOW this *Bulletin* 1949 v 45 724) was not done.] Total plasma protein was usually low and there was marked inversion of the albumin/globulin ratio. Liver biopsy showed, in different individuals, the progress from fatty infiltration to portal cirrhosis, and was also useful in establishing diagnosis and prognosis.

Treatment consisted mainly in the giving of a liberal well-balanced diet rich in protein and vitamins. The advantage of adding lipotropic substances such as choline is still doubtful. It is of the greatest importance that intercurrent infection should be controlled and toxic substances such as alcohol must be withdrawn. In the fatty phase of this disease the condition is apparently completely reversible, the prognosis being progressively worse as the amount of fibrosis increases, but even in advanced cases with established portal cirrhosis a suitable régime may retard or arrest the downward trend. *Dean A. Smith*

STRANGWAY W. E. & STRANGWAY ALICE H. Ascorbic Acid Deficiency in the African Disease Ouyalai. *Arch. Intern. Med.* 1949 Apr v 83 No. 4 577-8 1 fig.

Ouyalai is a form of thrombopenic purpura, of hitherto unknown aetiology described in many parts of Africa and characterized by the formation of

haemorrhagic bullae on mucous membranes, haemorrhages from the intestinal and urinary tracts and a high mortality. Of 150 patients suffering from onyala admitted to a hospital in Angola up to 1940, 90 per cent died.

Dietary investigation of patients in the area of Angola concerned, revealed a very low intake of ascorbic acid, especially during the hungry season when the incidence of onyala is at its highest. Accordingly, treatment with large doses of lemon juice, pure ascorbic acid not being available, was tried and proved effective. The amounts given were large, ranging from 2 to 20 litres, and recovery within a few days occurred in all but one of 43 patients. When synthetic ascorbic acid became available it proved equally effective, the total dosage varying from 2 to 8 gm. Intravenous administration was necessary in severe cases, and 9 out of 10 patients recovered within seven days.

These findings strongly indicate that onyala is due to dietary ascorbic acid deficiency. One observation, however, throws doubt on this as the complete explanation of the aetiology of the disease. In three untreated patients ascorbic acid excretion in the urine was found to be between 50 and 100 mgm per 24 hours, a rate of excretion greater than that of normal Africans. It may be postulated that, while a low ascorbic acid intake is a predisposing condition, the onset of the disease is determined by excessive excretion, with consequent rapid tissue depletion, by some toxic mechanism. This hypothesis gains some support from the very high dosage necessary to achieve a cure, a dosage much in excess of that needed for the treatment of scurvy. [See also RIGBY below, p 873.]

Dean A. Smith

SPRUE

KEELE, K. D. The Prognosis and Treatment of Sprue in India. *Brit Med J* 1949, June 4, 986-9, 1 chart

In a clinical survey of 600 cases of sprue during the recent war it was ascertained that only 31 per cent had reached the stage of complete remission of the disease before evacuation from India. The object of the present paper is to assess the prognosis and results of treatment of 62 others in the follow-up period of two years in England, so that the value of methods of treatment at that time employed may be judged in perspective. In general, cases were treated, on admission, by diet alone. When this failed, the patient was given "an investigation diet" from which therapeutic substances, such as liver, were omitted. With this diet it was possible to assess the effect of parenteral liver, nicotinic acid and riboflavin. Cases which responded satisfactorily to diet were classified as mild sprue; those which failed to do so as severe sprue.

Criteria of progress (short term) were assessed by appearance of signs of the remission phase. These constituted, gain in weight, cessation of diarrhoea, steatorrhoea and abdominal distension were the last signs to disappear. Criteria of complete remission were restoration of weight to within 10 lb of normal, stools normal in number, colour and fat content and absence of abdominal distension. Criteria of long term progress (after 2 years) were based (1) upon complete fitness since return from India, (2) loss of time from work with symptoms suggestive of sprue or any other disease, and (3) necessity for hospital treatment.

For dietetic treatment the short-term (3 months) results are shown for 52 patients treated initially with diet alone by means of the Napier 3, 4, 5 high-protein low-fat sprue diets ranging from 1,513 to 2,584 Calories and containing

1.2-1.6 mgm. thiamine, 6.0-6.3 mgm. riboflavin 18.3-26.9 mgm. nicotinic acid and 31-43 mgm. ascorbic acid. Thirty-seven patients were evacuated to England after three months treatment, 23 in a state of complete and 14 of partial remission. The remaining 15 failed to respond to treatment.

The long term (2 years) results show that during two years, 29 have been in complete remission, four have periodically developed symptoms and four have definitely relapsed and have been admitted to hospital.

The results of short term (6 months) parenteral therapy were seen in 25 patients 15 who had failed to respond to dietetic treatment and 10 too ill on admission to be treated on diet alone. All these received investigation diets but without foods with possible therapeutic value such as liver, bananas and vitamins. They received parenteral liver over long periods and some were given trials of injections of nicotinic acid and riboflavin for a short time. All were treated for six months before evacuation from India. Ten were in complete remission, 13 in partial, and 2 failed to respond.

Of the 62 patients 69.4 per cent. have remained well for two years in England and 8 per cent. have had mild gastro-intestinal symptoms. 16.1 per cent. have relapsed since leaving hospital in India.

The cyclic evolution of the disease should be appreciated, and a glossitis lasting 2-3 weeks early in remission has an obvious bearing on assessing the efficacy of any therapeutic agent. Liver therapy is dramatic and may be life saving, but has no detectable action during remission.

Of 51 patients treated by diet alone 71 per cent. underwent remission. Fifteen who failed to improve were deprived of liver, bananas, and vitamin extracts for a period up to 17 days without any deterioration in their condition.

In 10 undergoing remission during liver therapy a positive nitrogen balance was found. In one of these a negative nitrogen balance had been present during relapse. During relapse also absorption of fat still remained in the region of 50 per cent. Raising the fat intake from 69 to 96 gm. daily did not alter the percentage absorbed. The evidence of the glucose-tolerance curve is doubtful. This was flat in relapse and remained so for the first two weeks of remission. Nicotinic acid and riboflavin produced no change in fat absorption nor in the clinical state.

In one severe relapse the effect of 10-15 gm. of sodium chloride daily by the mouth was tried for 10 days. Fluid stools rose from 3 to 9 a day weight dropped, anorexia increased and weakness became extreme. Serum sodium rose from 258 mgm. to 310 mgm. per 100 ml.

Sulphaguanidine (as in bacillary dysentery) improved the diarrhoea often within 24 hours. The danger of dehydration was rapidly overcome. As it did not produce remission of symptoms its usefulness lay solely in controlling diarrhoea. The mode of action of liver in sprue is not clear. The extract used was a crude one of Indian manufacture and was equivalent to a standard proprietary preparation as regards haemopoietic activity. Dosage was 10 ml. given intramuscularly each day for 4 days followed by 4 ml. daily for some weeks.

The effects of liver depend on the phase of the sprue cycle. It is active and beneficial in relapse but affords little benefit in remission. The more marked the relapse syndrome the more effective was liver therapy but its action was not proportional to the severity of the anaemia. Gastric hydrochloric acid was increased under liver therapy while the stools, though pale, became normal in number and consistency within 3-7 d. ja. Reticulocytosis was slight (not above 3 per cent.) but the red cell count slowly rose over a period of weeks with steady diminution in the mean corpuscular volume to normal.

The action of liver manifested itself in the gastro-intestinal tract from tongue to colon, producing evidence of increased absorption of water and water

soluble-substances, but no such marked effect was seen in fat absorption. The haemopoietic response was slow and unlike that produced in pernicious anaemia
P Manson-Bahr

HAEMATOLOGY

FONSECA, L C Subnutrição e anemia na região noroeste do estado de São Paulo (Sobre a importância das carências alimentares na patogenia das anemias com especial referência à ancilostomótica) [Malnutrition and Anaemia in the North-Western Region of São Paulo (Brazil) (On the Importance of Dietary Deficiency in the Pathogenesis of Anaemia, with special reference to Hookworm Anaemia)] *Hospital* Rio de Janeiro 1948, Apr, v 33, No 4, 559-610, 6 figs [125 refs]

A haematological investigation was made in 212 unselected recruits from the interior of São Paulo, Brazil. The men were divided into groups, according to their previous dietary background. The results are summarized in the following table —

Diet	No of cases per cent	Mean R B C millions per cmm	Haemoglobin gm /100 ml	Mean Corpuscular Haemoglobin, $\gamma\gamma$
Very good	1	4.64	14.48	31
Good	19.8	4.69	14.62	31
Average	20.2	4.37	13.28	30
Bad	38.2	4.20	12.64	29.7
Very bad	20.8	4.07	11.91	29.2

If anaemia is considered to be present when the red cell count falls below 4 million, or the haemoglobin below 14 gm /100 ml, then 70 per cent of the recruits were anaemic. The incidence in the general population is likely to be even greater, since the group studied was composed of apparently fit young men.

The author goes on to discuss the part played by iron-deficiency and by ankylostomiasis in causing this high incidence of anaemia. He recapitulates in detail the work of W. Oswaldo Cruz, who in 1932 [this *Bulletin*, 1932, v 29, 760] put forward the hypothesis that the essential cause of hookworm anaemia is an inadequate iron intake, and that only a secondary rôle is to be attributed to the blood-sucking activities of the parasite. This view received some support from the findings of RHOADS, CASTLE, PAYNE and LAWSON in Porto Rico [*ibid*, 1935, v 32, 263].

In subsequent papers [*ibid*, 1934, v 31, 797, 1935, v 32, 262, 640] Cruz showed that the so-called hookworm anaemia as seen in Brazil, is intensely microcytic and hypochromic, with an average mean corpuscular volume of 56 μ and a mean corpuscular haemoglobin of 13 $\gamma\gamma$. On treatment with iron alone, without vermifuges, the red cell indices are rapidly restored to normal. This response is accompanied by a reticulocytosis of up to 30 per cent, which may cause a transient macrocytosis [compare LEHMANN, this *Bulletin*, 1949, v 46, 664]. Vermifuges, on the other hand, have quite a different effect: they may cause an increase in the red cell count, but have no effect on the red cell indices, and do not produce signs of blood regeneration.

On Cruz's theory ankylostomiasis is to a large extent irrelevant as a cause of anaemia, such as that found in São Paulo. Fonseca in the main accepts this view. He attaches, however, rather more importance to the hookworm as a cause of blood loss and thereby loses not only of iron but perhaps also of other nutrients, such as vitamins and protein. The paper concludes with an examination of the public health aspects of the problem, and with a plea for more attention to be given to the nutritional status of the Brazilian people.

J. C. Waterlow

PATEL, J. C. & BHEMDE, V. M. "Refined" Liver Extract in Tropical Macrocytic Anaemia. *Blood* 1949 Mar v 4 No. 3, 259-68. [17 refs.]

Forty-five patients with tropical macrocytic anaemia (T.M.A.) were treated with "refined" liver extracts, Anaheamin Examen Reticulogen, and Examen N.P. (new potency). All had a red cell count below 3.0 million per cmm. The patients were in hospital on a milk or vegetable diet.

In four patients on Anaheamin an optimum response was obtained after 2 ml. repeated weekly for 4 weeks, 12 ml. in 8 days, 9 ml. in 10 days and 20 ml. in 10 days, respectively. In one of these cases no response was observed after the first 2 ml.

With Reticulogen, no response was obtained in one case with 4 ml. in 8 days but optimal response in another on 8 ml. in 8 days.

With Examen an optimal response was obtained in a series of cases with divided doses of 8 ml., 12 ml., 14 ml., 14 ml., 22 ml., 22 ml., 26 ml. and 32 ml., a sub-optimal response with 4 ml. (single dose) and no response or poor response to 10 and 20 ml. (divided) but both the latter failed to respond normally to "crude" liver extract.

With Examen N.P., an optimal response was obtained with divided doses of 1 ml., 10 ml., 6 ml. (in 7 cases) and 3 ml. (in 4 cases) and with single doses of 2 ml. (in 5 cases) and 1 ml. (1 case). A sub-optimal response was obtained with 1 ml. (1 case) and 2 ml. (4 cases). No response was obtained with 3 ml., 2 ml., and 5 ml. (in 1 case each) but in the two latter cases no response was obtained with crude liver extract either.

The authors conclude that, as in the case of pernicious anaemia, the response in tropical macrocytic anaemia, or in nutritional macrocytic anaemia of temperate climates, which they consider the same syndrome, to liver extracts

"refined" or "crude" is in proportion to the amount of liver from which the extract was made. But they consider that there is evidence that the newer refined extracts contain some substance that was not included in the earlier preparations, and that this accounts for discrepancies in the observations of some previous workers.

They also conclude "As judged from therapeutic observations it is suggested that in the majority of cases of T.M.A. the deficiency is similar to that in Addisonian pernicious anaemia though the mode of production of the deficiency may not be the same."

L. E. Nafser

SPIES, T. D., GARCIA LOPEZ, G., MILANKS, F., LOPEZ TOCA, R. & ARAMBURG, T. A Note on the Oral versus Parenteral Administration of Vitamin B₁₂. *Southern Med. J.* 1949 June v 42, No. 6 529-31. 2 charts.

The authors refer to their paper on the tentative appraisal of vitamin B₁₂ as a therapeutic agent [this *Bulletin* 1949 v 46, 566]. They confirm their observations on the response to B₁₂ of cases of pernicious anaemia, tropical spore and nutritional macrocytic anaemia (four of each, all in relapse) and they point out that while oral administration is highly satisfactory parenteral

injections will be indicated in many cases. There are advantages in the use of this route in cases where there is severe cardiac failure, severe neurological changes or severe gastro-intestinal disturbances. The patient will absorb the material administered parenterally and a deranged tract cannot act as a block to its absorption.

While there is considerable variation in response, the patients in the authors' group can be said to have taken from 30 to 50 times as much material by mouth as by injection. This amount is reduced to about 5 to 10 times the parenteral dose by the oral administration of an incubated mixture of vitamin B₁₂ and normal human gastric juice. Two patients with pernicious anaemia are referred to who developed "acute combined system disease" after 30 microgrammes of B₁₂ by the mouth when the same quantity was incubated with human gastric juice and given to the patients the blood responded and the "acute signs of combined system disease" disappeared. *H J O'D Burke-Gaffney*

ITANO, H. A. & PAULING, L. **A Rapid Diagnostic Test for Sick Cell Anaemia**
Blood 1949, Jan, v 4, No 1, 66-8 [14 refs]

In sickle-cell anaemia, the erythrocyte maintains its normal shape in the presence of sufficient oxygen, but when the oxygen tension is reduced the haemoglobin aggregates into clumps, the cell membrane collapses, and the erythrocyte takes on an oat or sickle shape.

The authors' method of testing blood for this sickling tendency is based on the fact that sodium dithionite ($\text{Na}_2\text{S}_2\text{O}_4$) reduces oxyhaemoglobin.

The reagent is prepared by adding 0.114 M aqueous sodium phosphate (Na_2HPO_4) to 0.114 M aqueous sodium dithionite until the pH is 6.8, the ratio of the two solutions required for this purpose is about 3 to 2. The reagent should be prepared shortly before use. About 0.05 ml is added to a small drop (about 0.01 ml) of blood on a slide (either oxalated or finger blood) and the mixture is observed under the microscope, or an excess of reagent may be added to a small volume of blood in a test-tube and a drop of the mixture observed under the microscope. The process of sickling may also be followed in a haemocytometer counting chamber by half filling it with a saline suspension of the red cells and then adding the reagent to fill the chamber.

The authors tested the blood in six cases of sickle-cell anaemia and noted characteristic changes. They assume that the sickling will also occur with the blood of a person with the sickle-cell trait only, but their tests in this investigation were confined to cases of declared anaemia. *L. E. Napier*

CORNBLEET, T., SCHORR, H. C. & BARSKY, S. **Pseudo-Ophiasis and Sick Cell Anemia** *Arch. Dermat. & Syph.* 1949, May, v 59, No 5, 519-21

"All 3 patients were male, but their ages ranged from 5 to 25 years. All had severe sickle cell anemia. It appears that the alopecia, once formed, remains indefinitely. It does, however, vary in degree, the variation paralleling the changing severity of the subject's anemia. The alopecia could be thought of as an inverse hippocratic one. It would have been desirable to make a histologic study of material from the scalp, but this material was not forthcoming. The alopecia is apparently not a family characteristic. How it is produced is pure conjecture."

EPIDEMIC DROPSY

SINGH, B. M. A Study of Clinical Features of Acute Cardiac Failure in Epidemic Dropsy. *J Indian Med Ass* 1949 Feb., v 18, No 5 158-60

At Bhaugapur epidemic dropsy occurred in 1939-40 and thereafter sporadic cases only were observed till the beginning of 1947 when they became more frequent and reached an acme in the second quarter of the year. The crop was shown to be mustard oil contaminated by argemone oil. In this short paper particular reference is made to 12 patients (out of 40 studied) who presented symptoms of acute cardiac failure. No organic valvular lesions were detected, no ascites and no cyanosis until just before death—no marked dropsy was present. The condition is very serious, with marked dyspnoea, respirations 50-60 per minute, pulse 120-130—a posture of orthopnoea was preferred although it did not seem to afford any relief. In two patients the attack was brief, lasting 2-4 hours only; in one it lasted for 48 hours—the remaining who died after symptoms increasing in severity. [Nothing is said of the post mortem appearances—perhaps no autopsy was held.] *H Harold Scott*

VENOMS AND ANTIVENENES

CORRILL, N. L. Malnutrition and Snake Poisoning in the Sudan. *Tans. Roy Soc Trop Med & Hyg* 1949 May v 42, No. 6 613-16 1 graph.

The author states that in the Anglo-Egyptian Sudan there are two seasons of the year when human beings suffer from nutrition deficiencies—the early rains (May-July) when milk and green food are scarce and the winter (November to mid-February) when latent deficiencies tend to become overt. The period of heavy rain is July-October.

Snakes are most numerous at the height of the rains and, naturally, cases of snake-bite are then more common, but figures show that fatalities from this cause are more frequent in the dry season when snakes are relatively fewer. It is suggested that—in the dry season persons are in a nutritionally poorer state than they are in the wet season when milk and vegetables are plentiful, and the superimposed snake poisoning—spart from the synergistic haemorrhagic effect of viperine venom with ascorbin deficiency—serves through trauma as a premonitory episode i.e. as a stimulant to katabolism, and thus tends to activate nutrient deficiency conditions thereby increasing the illness of the bitten person.

The common belief in the annual recurrence of symptoms is ascribed analogously to the annual season of deficiency. *H Harold Scott*

TAYLOR, E. H. A Preliminary Account of the Herpetology of the State of San Luis Potosí, México. *Univ Kansas Sci Bull* 1949 Apr 20 v 33, Pt. 1 169-215

ROCHA & SILVA M. BERALDO W. T. & ROSENFELD C. Bradykinin, a Hypotensive and Smooth Muscle Stimulating Factor released from Plasma Globulin by Snake Venoms and by Trypsin. *Amer J Physiol* 1949 Feb. 1 v 158 No. 2, 281-73 8 figs. 31 refs.

"The pseudo-globulin fraction (precipitated by 30 to 45% saturation with ammonium sulphate) of normal plasma contains the precursor (bradykinogen) of a hypotensive and smooth muscle stimulating factor (bradykinin) that can be

released by proteolytic and coagulating venoms of the *Bothrops* genus and by trypsin. If an appropriate dose of the enzyme or the venom is used, the maximum release is observed after 1 to 3 minutes incubation, at 37°. If incubation of the globulin with the venom of *B. jararaca* or trypsin is prolonged for 10 to 20 minutes the released factor is destroyed, this suggests that it has a polypeptide nature or at least a peptide linkage, the integrity of which is necessary for its pharmacological activity.

"Bradykinin is thermostable, dialysable through cellophane, resistant to prolonged boiling in 0.1 to 1 N HCl solution, but rapidly destroyed if heated in an alkaline solution.

"The guinea pig gut is the most sensitive smooth muscle organ assayed and the rat intestine the least so. Doses of bradykinin equivalent to those released from 100 to 200 cc of plasma produce a steady fall in arterial blood pressure of the cat, the rabbit and the dog. The possibility that bradykinin is a mediator in several kinds of shock is discussed."

AHUJA, M. L. & BROOKS, A. G. Detoxification of Krait Venom *in vivo* by means of Carbolle Soap Solution. *Indian J Med Res* 1948, Apr., v 36, No 2, 181-2.

The senior author refers to previous work by himself and BROOKS [this *Bulletin*, 1946, v 43, 478] in India and that of CHRISTENSEN and DE WAAL [*ibid*, 1948, v 45, 108] in South Africa on the protective effect of soap solution in pigeons and guineapigs respectively given certain lethal doses of cobra venom.

The note records the protective effect of soap solution infiltrated into the thigh muscles of guineapigs 1 to 3 minutes after that area had been injected with venom of the common krait (*Bungarus caeruleus*).

A table shows how the survival time was extended by the administration of soap solution after doses of krait venom of 0.06 to 0.02 mgm, compared with corresponding doses when no treatment was given. For example, with 0.02 mgm of venom, 4 guineapigs died in 5 to 8 hours respectively, while with soap treatment and the same dose of venom, 3 out of 4 animals survived and the fourth did not die for 30 hours.

EFRATI, P. Poisoning by Scorpion Stings in Israel. *Amer J Trop Med* 1949, Mar., v 29, No 2, 249-57 [15 refs].

The author has, during the 12 years 1935-1947 seen a large number of cases of scorpion sting, but in 22 only did generalized toxic signs appear and his remarks in this paper are based on these. The common scorpions of Palestine are *Buthus quinquestriatus* (the most poisonous), *Prionurus bicolor*, *Nebo herichonticus*, *Buthus judaicus* and *Scorpio maurus*, one of the patients was stung by *P. crassicauda*, in ten other cases in which the scorpion was identified it proved to be *B. quinquestriatus*, all the severe cases and all that ended fatally were the result of stings by this species. The systemic symptoms which came on 10-20 minutes after the stinging were usually restlessness, laboured respiration, cyanosis, vomiting, flushing of the face, rhinorrhoea, chilliness and tachypnoea, sometimes formication, tachycardia and abdominal pain.

Six of the 22 patients died, serum was obtainable in a few instances only, so treatment was chiefly symptomatic. Five received serum prepared at the Pasteur Institute, Algiers, one died—the amount of serum being insufficient—whereas of 17 who did not receive it 5 died. Atropine and Gynergen [this is not defined] were given to 5 patients, two seemed to improve, but in three no benefit was observed. [Nothing can be inferred from this because many of those stung get well without treatment.]

H. Harold Scott

SERGEANT Et Douze années de sérothérapie antiscorpionnique [Twelve Years Use of Scorpion Antivenin.] *Ann. Inst. Pasteur* 1919 Jan. v 78 No. 1 50-52.

The antivenin used is that prepared by inoculation of horses with the venom or anavenom of *Proxurus australis*, the most toxic of North-African scorpions [see this *Bulletin* 1949 v 48 775]. This is active against the venoms of other scorpions in this district. Thus the author records the case of a boy of 6 years, stung by a *Buthus occidens* as he became comatose in a few minutes but rapidly revived when given a subcutaneous injection of 20 cc. of *P. australis* antivenin. The preparation was made available to medical practitioners in 1936 and in the next 12 years observations had been sent in on 4 057 patients treated by the antivenin. Among these, 1,003 were so serious as, in the opinion of the medical attendants, to threaten life and of these 923 (92 per cent.) recovered. 24 were Europeans, the rest (97.5 per cent.) were indigenous Moslems. H. Harold Scott

DERMATOLOGY AND FUNGUS DISEASES

DOSTROVSKY A. & SACHSE R. Lichen Planus in Subtropical Countries. Study of an Annular Type with Inverse Localization (Uncovered Surfaces of the Skin). *Arch. Dermat. & Syph.* 1949 Mar v 59 No. 3, 308-28. 3 figs. [Refs. in footnotes.]

During the years 1930 to 1946 a total of 131 cases of lichen planus were treated at the outpatient department of the Rothschild-Hadassah University Hospital, Jerusalem. This figure represents approximately 0.2 per cent of all patients with dermatological disease.

In 51 cases a special type of lichen planus was observed. Morphologically this appeared in an annular pattern mainly confined to the exposed parts. The eruption had a special predilection for the lower age groups, and affected particularly persons of dark complexion coming from subtropical countries. It differed from classical lichen planus in that itching was almost entirely absent. The onset was seasonal with recurrences or spreading in spring and summer and improvement in the rainy season. It ran a longer course than classical lichen planus, and usually lasted several years. Grenz rays were used in the treatment of 18 patients, in 10 of these the lesions disappeared, and in 3 there was some improvement. H. T. H. Wilson

LIMA TORRES, A. Treponemose discrômica. Puntá-puntá, mal de ponta. (Dyschromic Treponematosis. Mal del Pinta.) *Rev. Brasileira Med.* Rio de Janeiro 1949 Feb., v 6 No. 2, 111. 1 chart. [3 refs.]

This paper was presented for reading to the Public Health Society of Brazil. It covers the subject of pinta generally, with many quotations from or allusions to the literature of the disease. The author proposes the name of *dyschromic treponematosis* caused by *Treponema carateum* and L. divides his essay into three parts: epidemiology, prophylaxis and legislation. Much of it is text book knowledge today. He starts with a list of the synonyms in Brazil, Colombia, Mexico, Haiti and elsewhere and follows this with a definition of the disease and a sketch of the history of the discovery of the cause from the early "mycotic" days to the later spirochaete and the various names given to the organism: *T. carateum*, *T. kerreyi*, *T. americanum*, *T. f. disc.*, *T. f. pinta* and *T. dyschromoderma*, deciding that the first is the correct one given by

Brumpt in 1930 The geographical distribution and transmission are next dealt with Modes of transmission referred to are 1 Direct, by contact 2 Indirect by (i) vectors, *Hippelates* and *Simulium*, (ii) Ritual means, mutual flagellation, the whips being contaminated by the blood of some infective person transferred to the wounds of a non-infected, (iii) Criminal [surely unlikely] where "rowers and interpreters" who object to newcomers inoculate the latter with infective blood or give them such blood mingled with their food, when their mouths are sore from eating some irritating food, (iv) Other modes mentioned are infection of an infant by its mother's milk, and transmission by blood-transfusion Hereditary transmission is also mentioned, but the author states that the evidence for this is lacking

The section on Prophylaxis contains nothing fresh, it includes search for cases, diagnosis by serum reactions and finding the organism, treatment by mercury, arsenicals and penicillin, and protection of the healthy by good sanitation, healthier and better dwellings and propaganda work by instituting sanitation posts for the treatment of patients by spreading information about the disease and educating the people The third section on Legislation is closely connected with the second and includes penalties for violation of the rules of hygiene

CAMPBELL, Charlotte C & SASLAW, S Use of Yeast-phase Antigens in a Complement Fixation Test for Histoplasmosis. III Preliminary Results with Human Sera. *Pub Health Rep Wash* 1949, May 6, v 64, No 18, 551-60 [11 refs]

In a previous paper by these authors [this *Bulletin*, 1949, v 46, 83] on the complement-fixation reaction with anti-*Histoplasma* rabbit serum and various forms of *Histoplasma* antigen, it was shown that the most suitable antigen for the test was a suspension of the ground-up yeast-like form of the fungus This kind of antigen was therefore used in the complement-fixation tests with human serum which were designed to determine the probable value of the complement-fixation reaction in the serological diagnosis of histoplasmosis, to find if the degree of dermal sensitivity to histoplasmin was proportionate to the titre of complement-fixing serum antibody, and to determine to what extent the specific value of the complement-fixation test for the diagnosis of histoplasmosis was vitiated by cross reactions with the antigens of *Blastomyces dermatitidis*

In three cases of acute histoplasmosis the serum titres for complement-fixation ranged from 1:330 to 1:1,280 but as the disease progressed towards the chronic stage these titres declined and approached the level of those given by normal sera.

Of the normal sera examined, 40 per cent. gave complement-fixation in titre from 1:10 to 1:40. Low titre complement fixation was given by the sera of 10 out of 73 persons who were histoplasmin-positive and by 6 out of 131 who were histoplasmin-negative. It was found that the proportion of apparently non-specific serum reactions was greatly reduced by allowing only 4 hours instead of the customary 18 hours for antibody-antigen combination in the cold before adding the complement. Cross reactions with *Blasowrites* antigens occurred and, as previously observed, they were more marked between anti-*Histoplasma* serum and *Blasowrites* antigen than between anti-*Blasowrites* serum (which was invariably of low antibody content) and *Histoplasma* antigen.

From the results quoted, the authors concluded that the potential value of the complement-fixation test as an aid in the diagnosis of histoplasmosis has been demonstrated.

J. T. Duncan

SASLAW S. & CAMPBELL, Charlotte C. A Colloidal Agglutination Test for Histoplasmosis. *Lab Health Rpt* Wash. 1949 Apr 1 v 61 No. 13 421-8

In an earlier paper SASLAW & CAMPBELL (this *Bulletin* 1949 v 46, 779) described the reaction of agglutination by anti-histoplasma serum, of a suspension of colloidal particles sensitized with the soluble antigens of *Histoplasma capsulatum*. The present report deals with the application of this serological reaction as a diagnostic test for human histoplasmosis.

The sera of 197 healthy persons 71 of whom were histoplasmin-positive, were tested with the sensitized suspension and 60 were found to cause relatively weak agglutination. Of these 60 25 were in the histoplasmin-positive group and 35 in the histoplasmin-negative group. So the apparently non-specific agglutination reaction was not related to dermal sensitivity to histoplasmin.

Tests with sera from six proved cases of histoplasmosis showed three all from chronic stages of the disease to possess weak agglutinating power similar to that of the normal sera, but the remaining three all from acute disease showed much stronger reactions and higher agglutinin titres. With these six human sera, the results of the colloidal agglutination tests were closely correlated to those of specific complement fixation tests, and it was felt that further research may show that the agglutination of sensitized colloidal particles constitutes a simple and useful diagnostic test in histoplasmosis.

J. T. Duncan

FIRSTSTONE G. M. & BEYRON E. S. Coexisting Disseminated Coccidioidomycosis and Tuberculosis. *Am J Rpt Tuberculosis*. 1949 Apr v 59 No. 4 415-23, 4 figs. [11 refs.]

A case of disseminated coccidioidomycosis which lasted for six years and was complicated by active tuberculosis is presented. The two diseases seemed to occur coincidentally the individual coccidioidal granulomas being devoid of acid-fast bacilli, and the tubercles containing only a few *Coccidioides* sporoblasts at the periphery. The coccidioidomycosis terminated in a miliary dissemination throughout the body including the brain and prostate, as well as the more usual sites but did not involve the bowel or renal pelvis. The tuberculosis presented a definite secondary or adult type of distribution in the lungs, pharynx, and bowel, as well as a hematogenous dissemination to the serosal vesicles.

"Streptomycin was of definite value in controlling the tuberculosis but did not affect the coccidioidomycosis, whereas potassium iodide and vitamin D₂ in massive doses seemed to decrease some manifestations of the coccidioidomycosis. It is suggested that the latter drugs be given further trial in cutaneous coccidioidomycosis."

HEAT STROKE AND ALLIED CONDITIONS

LADELL, W S S The Effect of Pituitrin upon Performance in Moderate Heat
South African J Med Sci 1948, Oct, v 13, No 4, 145-50, 1 fig

During work in humid heat there is probably some release of anti-diuretic principle from the pituitary, and this paper reports preliminary observations on the effect of pituitrin on performance in the heat. The subjects were eight young African medical students, none of whom had been outside Nigeria. The experimental room was maintained at about 88°F dry-bulb and 83°F wet-bulb, with calm air. In each experiment there were four 30-min spells of step-climbing on to a stool 1 ft high 24 times a minute, with 15-minute intervals of rest. Weighings were done, and sweat losses thus ascertained.

Each subject was tested four times, twice without and twice with pituitrin (5 units given subcutaneously). The pituitrin decreased the sweat production of the heavy sweaters and increased that of the light sweaters so that after pituitrin the two groups lost similar amounts of sweat.

This statistically significant difference could not be accounted for with any certainty, but there is a very brief discussion of a possible explanation.

MISCELLANEOUS DISEASES

LÖFFLER, W, ESSELIER, A F & MACEDO, M M Sobre a patogenia e etiologia do infiltrado pulmonar fugaz com eosinofilia sanguínea (Síndrome de Loeffler)
[The Pathogeny and Aetiology of Loeffler's Syndrome] *Gaz Méd Portuguesa* 1949, v 2, No 1, 1-16, 10 figs (8 coloured) & 1 folding chart [15 refs]
English summary

The coincident presence of eosinophilia and transient pulmonary infiltration has been accounted for in various ways. The authors have shown by experiments on guinea-pigs, infesting them with larva-containing ova of *Ascaris lumbricoides*, that the results were patches of atelectasis, and evanescent pulmonary changes with eosinophilia, and by sacrificing the animals at intervals he has demonstrated the larvae and eosinophilia in the lungs. The coloured plates of the stained sections are particularly good. [This article cannot be said to add very much to our knowledge of Loeffler's syndrome. All that the authors have shown is that *Ascaris* larvae in passing through the lungs set up transitory changes there associated with eosinophilia—facts well known in the life-history of this helminth.]

H Harold Scott

JAFFÉ L. Scleroma (Rhinoscleroma). *Trans Roy Soc. Trop Med & Hyg* 1949 May v 42, No. 6 617-19 [11 refs.]

The author writing from Almirante, Panama, prefers the less restricted term scleroma to that of rhinoscleroma because the disease is by no means limited to the nose. The case here described supports his view. The patient was a man of 24 years whose nostrils were almost closed by crusted scar like tissue with granulations on the right vocal cord and thickening of the subglottic mucosa. The report by the pathologist on tissue from the nostrils was that it was a typical rhinoscleroma. Treatment by sulphathiazole was tried, then by iodadin (reprodal) intramuscularly and tartar emetic intravenously and surgical symptomatic local measures but with little and not lasting benefit. After 15 months of this he is to apply elsewhere for X-ray or radium treatment.

Rhinoscleroma is believed by some to have autochthonous foci only in Central America, Sumatra, and in South-eastern Europe in Volhynia and Galicia. It is, however not uncommon in Guatemala and El Salvador and the author saw cases of it in Honduras. The results of the various forms of treatment suggested and tried are variable and uncertain.

DE LA RIVA, G. E. Contribution to the Study of Tropical Eosinophilia. *Southern Med. J.* 1949 May v 42, No 5 429-34 [27 refs.]

Early in 1949 an epidemic of fever and eosinophilia involving about 300 cases occurred in Pinar del Rio in the Western province of Cuba. Writing from Havana, the author describes his investigations on a group of 43 of these cases. Thirty-one of them he regarded as parasitic infections with no positive findings except for a moderate eosinophilia. These recovered completely after parasiticidal therapy. Eight cases were regarded as examples of Loeffler's syndrome on account of their marked pulmonary consolidations, high eosinophilia, and rapid recovery. The remaining four cases in this group were regarded by the author as examples of tropical eosinophilia. All four showed asthmatic symptoms, leucocytosis and eosinophilia, and in all cercariae of *Fasciola hepatica* were isolated from bile samples. Three other cases exhibiting respiratory symptoms and a high degree of eosinophilia were also regarded by the author as classical examples of tropical eosinophilia. Surgical removal of a congenitally atrophic testicle in the first case of retained products of conception in the second, and of a dermoid cyst in the third was followed by complete recovery in each case. The author accordingly is of the opinion that tropical eosinophilia is not a specific disease but is an allergic response of an organism to embryonic elements of any nature which act as allergens with specific antibody production.

[The author has demonstrated that respiratory dyspnoea and eosinophilia may follow a variety of causes. In each of the seven cases which he describes a reasonable explanation is given to account for the symptoms and the eosinophilia. It is therefore doubtful whether these cases are identical with those described by WEINGARTEN this Bulletin 1943 v 40 407] and subsequent writers who have failed to demonstrate similar findings after investigating a very large number of cases of classical tropical eosinophilia.

RIGBY, E P A Case of Secondary Thrombocytopoenia resembling Onyala.
East African Med J 1949, Apr, v 26, No 4, 84-6

Onyala has rarely been reported from East Africa, and only once from Kenya (WELCH, *J. Trop Med & Hyg*, 1920, v 23, 138) The case described below was probably of secondary origin

The patient, an adult Meru male, was admitted to hospital with a swollen and painful right knee Kahn test on 18th October 1948 showed +++ Three injections of bismuth [preparation and dose not stated] were given, but this was stopped owing to development of a mild gingivitis Subsequently four injections of 0.45 gm arsphenamine were given, the last on 25th November 1948 On 1st December the patient began to bleed from the gums, which showed no sponginess, but two haemorrhagic bullae were found on the tongue, one on the dorsum and one underneath On 3rd December he was still bleeding and a third bulla, showing umbilication, had developed on the lower lip Two ampoules of Planavit were given and three injections of the patient's own citrated whole blood, two of 20 ml and one of 16 ml, were administered intramuscularly Bleeding finally ceased on 5th December when the red cell count was 3,830,000 per cmm, the bleeding did not recur A successful platelet count was not done

On 19th January 1949 the Kahn test was negative and on 27th January an injection of 0.3 gm of arsphenamine was given without recurrence of the bleeding

This is the first time that the author has seen an onyala type of disease associated with the administration of arsenicals GELFAND [this *Bulletin*, 1949, v 46, 573] points out that this condition is found only in certain Bantu tribes, and the author suggests that its occurrence may be due to a personal idiosyncrasy, tribal in extent The patient was of the same tribe as the only case previously reported in Kenya by Welch

[Probably some cases are missed or confused with other diseases]

HUGHES, M A Case of Thromboangitis Obliterans in an African Woman
Trans Roy Soc Trop Med & Hyg 1949, May, v 42, No 6, 621-2 [10 refs]

Thrombo-angitis obliterans (Buerger's disease) is very uncommon in women, and the author has not been able to find any record of its occurrence in a negress He now reports a case in an African woman of the Northern Territories of the Gold Coast, a heavy tobacco smoker who also chewed tobacco, who came to hospital for treatment for a chronic ulcer of the foot Signs of gangrene appeared after local operation, and the author eventually amputated the limb 10 inches below the anterior superior iliac spine The stump healed by first intention, and the patient, previously in bad condition, immediately and dramatically improved

Pathological examination of the limb showed appearances typical of Buerger's disease, the association with tobacco is noted No Kahn test was done, but had it been positive it might have been the result of yaws

Charles Wilcocks

DAVIES, J N P Pathology of Central African Natives. Mulago Hospital Post Mortem Studies, X *East African Med J* 1949, Apr, v 26, No 4, 76-83 [10 refs]

The author groups renal disease into two main groups (1) those in which there is a gross alteration in the anatomy of the kidney, e.g. hydronephrosis, (1957)

tumour, etc. (2) those terminating in a granular scarred kidney *etc* containing cysts, and generally referred to as nephritis. Renal affections due to bilharzia are uncommon in Kampala, Uganda, unlike GELFAND's experience in Rhodesia. The clinical assessment of nephritis is most difficult; malnutrition oedema is common and can closely simulate a nephrotic syndrome. At autopsy the picture is often obscured by other lesions while the microscopic diagnosis is difficult. Nearly every kidney removed shows hyalinized glomeruli, even in the case of young children, but the incidence of arteriosclerotic nephritis appears low.

Of 2,994 autopsies at Mulago 301 cases were diagnosed as having some form of nephritis, of which 210 were put down as "unclassified," this group being made up of those where no histological examination was made and of those where signs both of diffuse glomerulotubular nephritis and proliferative glomerulitis were found. The majority of deaths occur in the younger age groups, and the commonest immediate causes of death in Africans w. nephritis were supervening infections, especially pneumonia. Very little is known about this condition in Africans, and, with the exception of HENNESSY's work in 1939 (this *Bulletin* 1939 v 36, 949) no detailed investigation appears to have been carried out.

Abnormalities of the kidney were studied at 3,375 autopsies. Primary renal agenesis is a very rare condition and no bilateral cases have been seen. There were only 4 cases of unilateral agenesis and dwarfed kidney and these lesions are less common in Africans than in Caucasians. Horseshoe kidney was found 3 times and in one such case numerous renal calculi were present. Solitary cysts were seen twice. No cases of bilharzial urinary infection were seen. In Uganda far the commonest cause of obstruction in the urinary tract is urethral stricture. Renal calculus is uncommon in Africans (at Mulago 11 cases in 2,294 autopsies). The commonest renal tumour was a secondary lymphosarcoma.

The commonest bladder condition was cystitis with hypertrophy due to gonococcal stricture. Tumours of the bladder and prostate have been discussed in a previous paper in the series. It is noted that the problem of urethral stricture is an immense one and treatment difficult as patients come late for treatment when infective and obstructive symptoms are usually well-established. Uro-genital tuberculosis of the fibro-caseous type is uncommon and renal tuberculosis almost always of the military type. C. F. SKELTON

PROTOZOOLOGY GENERAL

HELLBRÖGGE, T. Ueber Toxoplasmosen. [On Toxoplasmosis.] *Deut. med. Woch.* 1949 Apr 1 v 74 No. 13 385-9 4 figs. [7 refs.]

The author describes a case with symptoms of toxoplasmosis in a child who was under his care in Munich. The account is preceded by a lengthy review of the present state of our knowledge of this disease and of the parasite.

When admitted to the hospital, the patient, a child 3½ years old, showed signs of post-encephalitis, being mentally and physically underdeveloped, with diarrhoea. X-ray examination of the cranium revealed two calcified spots while examination of the eyes showed the characteristic lesions of chororetinitis.

pigmentosa The condition was thought to be congenital toxoplasmosis, the diagnosis of which was supported by a positive neutralization test with the child's serum, while the results of a similar test with the mother's serum were less pronounced Since the mother has been breeding rabbits for some years, it is thought that she contracted the infection from them, transmitting it to the child during its foetal development

"The effect of sulfadiazine, antiserum and a combination of these two materials on the course of congenital toxoplasmosis in mice was determined It was shown that while sulfadiazine and antiserum individually had some beneficial action, a combination of these substances was considerably more effective than either used alone"

ENTOMOLOGY AND INSECTICIDES GENERAL

ZUMPT, F Medical and Veterinary Importance of Horse-Flies *South African Med J* 1949, May 7, v 23, No 19, 359-62 [37 refs]

The author, reviewing the literature on the rôle of *Tabanus*, *Haematopota* and *Chrysops* as vectors of disease expresses the view that their capacity to disseminate certain disease organisms to man and animals, particularly mechanically as a result of interrupted feeding, has been underestimated in the past. In

this light, the literature on the mechanical transmission of trypanosomes (*Trypanosoma cruzi* *T. brucei* *T. vivax* and *T. congolense*) anthrax, tularemia, hemorrhagic septicaemia of buffaloes in the Dutch East Indies, amphisomus and infectious anaemia (swamp fever) of horses, is discussed and a plea is put forward for further study on the epidemiological importance of Tabanids (and of *Stomoxys*) in the spread of these diseases. JOHNSTONE, H F, WINSCH, W E & SMITH, L W The Dispersion and Deposition of Aerosols *Chem Reviews* 1949, Apr, v 44, No 2, 353-71, 8 figs

[This paper is entirely theoretical and highly mathematical it presents no new data but compares some conclusions with data of other workers]

From certain assumptions on the conditions governing deposition of aerosol particles out of doors, some predictions can be made about the optimum particle size for various purposes For example, when aerosol falls down through foliage while there is a gentle cross-wind, less of the larger particles will be impacted on leaves than the smaller particles On the other hand, if the aerosol is thrust down by a downdraught from the aeroplane, the opposite is true

For aerosols in confined spaces it can be calculated that there is an optimum particle size for producing various percentages of mortality The relations between particle size and wind velocity and mortality are also discussed, and the theoretical relationship is shown to agree well with experimental results obtained elsewhere

J R Busvine

LA MER, V K & HOCHBERG, S The Laws of Deposition and the Effectiveness of Insecticidal Aerosols *Chem Reviews* 1949, Apr, v 44, No 2, 341-52, 5 figs [15 refs]

Laboratory experiments were done with an apparatus designed to give aerosol particles of constant, determinable size The relation of particle diameter to insecticidal action was assessed by the concentration-time product for

exposures of mosquitoes to DDT aerosols. It was shown that the logarithm of this function is inversely proportional to the logarithm of the droplet radius (over the range 0.3 to 5 microns). In some tests with a wind tunnel, mosquitoes in cages were exposed to aerosols drawn past them at different speeds. The quantity of DDT per area of cross-section of the tunnel, necessary to give 99 per cent. kill of *Aedes aegypti* was determined for various combinations of particle size and wind velocity. The logarithm of this quantity was found to be inversely proportional to the logarithm of the product of the square of the diameter and the wind velocity.

This is due to the mosquitoes picking up more and more poison as the wind velocity increases and also as the diameter (and therefore liability to impaction) of the particles increases. The relationship falls off above a certain point where the mosquito begins to pick up all the particles approaching it in its area of cross section. This value appears to be about 700 micron-miles per hour which indicates an optimum particle size of 10 microns. [Apparently assume, an air velocity of 7 m.p.h.].

In outdoor use the logarithm of the quantity of aerosol falling on standard areas is shown to be inversely proportional to the distance away from the point of generation. Some practical examples are quoted, in which a mobile generator was used, to show that adequate kills of larvae and adult mosquitoes in different areas up to 800 or 1 000 yards away can be achieved by output of an aerosol at the rate of 34 lb. DDT per mile provided that correct particle size is chosen.

J. R. BURTON

PEFFLY R. L. & GAHAN J. B. Residual Toxicity of DDT Analogs and related Chlorinated Hydrocarbons to House Flies and Mosquitoes. *J. Econom. Entomol.* 1949 Feb. v 42, No. 1 113-16.

Laboratory tests were done to determine the toxicity to *Aedes aegypti* and to *Musca domestica* of a number of DDT analogues used as residual insecticides. Several of the best were used for extended tests though none of them was as good as DDT. One of the best samples was DDT by product oils, a mixture of unknown composition. Other comparative results may be indicated by a key as follows. A=best persistent action B C D=least efficient. Thus —

Where —				Known as	Effective grade against	
R	Q	P	X		<i>Aedes</i>	<i>Musca</i>

REPORTS, SURVEYS AND MISCELLANEOUS PAPERS

ROSS INSTITUTE INDUSTRIAL ADVISORY COMMITTEE [WIGGLESWORTH, A.,
Chairman] LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE
Information and Advisory Service 1949, May, No 1, 12 pp **Residual
Insecticides**

This is the first of a series of Bulletins to be issued by the Ross Institute Industrial Advisory Committee

In a foreword to the Bulletin by the Organizing Secretary, it is stated that the bulletins will deal with one or two important subjects and also will contain news and comments by the Director on the latest developments in tropical medicine and recent activities of the Ross Institute. Usually the main subject will be one of those diseases which are important in the daily work of the planter or miner.

This number deals with residual insecticides, their nature, use, indications and economics. In brief but adequate form, and yet with considerable practical detail, the subject is dealt with in a manner which gives a wealth of information which the intelligent layman will be able to grasp and pursue with ease. DDT and benzene hexachloride are dealt with separately and they are described effectively for the purpose for which the Bulletin is intended.

This series of Bulletins, having the weight of authority and the reputation of the Ross Institute behind them, should prove to be invaluable for those engaged in industry and management in the tropics.

H J O'D Burke-Gaffney

MACGREGOR, R B **Medical History of the War in Malaya** *Med J Malaya*
1949, Mar, v 3, No 3, 145-72

This is a graphic account of the medical situation in Malaya from the beginning, in 1939, of serious preparations to resist invasion, up to the re-occupation in 1945. It is compiled from the reports of many medical officers and traces the story of medical services during the war, retreat, and siege, the decay of Public Health services during the Japanese occupation and the eventful history of the civilian internees. Many of the purely medical details, particularly in regard to nutrition, have already received notice in this *Bulletin*. As a vivid and entirely unbiased description of this unhappy phase of Malaya's history it will be read with the greatest interest.

Dean A Smith

HANCE, B **The Development of Western Medicine in India** *J Trop Med
& Hyg* 1949, Apr, v 52, No 4, 79-82

The history of western medicine in India goes back to the Islamic conquest which spread from Persia to India, and brought the teachings of the great Arab physicians to displace the Ayurvedic system. The latter, though at its zenith (7th-5th centuries B C) it was based upon observation and experiment, had long been decadent when the Islamic invasion took place, but the new system in its turn fell into a decline. The first European physician known to have practised in India was a Portuguese who lived in Goa, where he published a book in 1563. Sir Bennett Hance records the outstanding events in the Medical history of India since that time, in so far as they relate to the development of western medical ideas there, in this short paper, which should be read in full.

The effort expended during the past hundred years or so to educate Indians in medicine has been impressive, and there are now 19 medical colleges teaching to degree standard, and 19 medical schools of licentiate standard. Together

An account is given of occult malaria in which there is a lack of obvious malaria symptoms. Occult malaria is more common in children than in adults and prodromal symptoms, which are common in adults may be missed in children partly because they are subjective and may not therefore come to the notice of the doctor.

There is an interesting discussion on the history of congenital malaria and malaria in very young infants. The diagnosis of congenital malaria can be made only when the disease occurs in conditions in which infection by mosquitoes is impossible. In over ten years the author has had 14 cases in which the diagnosis of congenital malaria has been made with confidence these cases occurred in over 200 000 patients. The possibility of the appearance of congenital malaria, however must not be overlooked and the physician should carefully enquire about the malarial history of the mother. Accounts of cases are quoted, some of which occurred in children born during the malaria free months in Ankara. It is recommended that in special cases drug prophylaxis should be carried out in malarial areas of Turkey during pregnancy. The author says that this is recommended not only in the hope of reducing the number of congenital cases but also the number of abortions which may themselves be due to the much greater frequency of infection in the foetus than is realized. Atebrin is the drug of choice.

Malaria in sucklings and very young children needs considerable attention. Typical rigors do not occur in sucklings, but they have as their equivalent "fever cramps" which of course are not uncommon in other diseases. Temperatures are often low in comparison with the fevers of other diseases. On the other hand, especially in river malaria, enlargement of the spleen occurs rapidly. Temperature charts are not usually characteristic of malaria at this age. In fact if the doctor is presented with a low fever in a sick child he should automatically think of malaria. There is a discussion on the various forms of fever which develop in this age group.

A particularly common characteristic of malaria in sucklings, which is also common in the young age group is dyspepsia and enteritis. Such malarial intestinal disturbances represent a considerable percentage of so-called summer diarrhoeas in children. In these cases parasites will be found in the blood and there will be a specific response to anti-malarial drugs. Both acute and subacute forms exist. A case is described of a child aged six months, admitted to hospital because of severe diarrhoea which had been going on for some days. The child had been raised exclusively on the breast. Until four weeks before admission it was in good health and going well. Since then it had become restless, was crying, sweating and suffering from loss of appetite and ceaseless diarrhoea. On examination the child was in fairly good condition, spleen one finger below the rib margin, temperature 37.9 C. and P. *trix* was present in the blood. On the third day of atebrin treatment the diarrhoea stopped.

A further interesting case is that of a child one and a half years old who was ill for months with diarrhoea: the stools, which were sometimes watery containing blood and mucus. On admission the temperature was 38.4 C., the spleen was just palpable below the costal margin. The patient was treated with anti-dysenteric serum glucose infusions bacteriophage and control of the diet. The diarrhoea responded, but began again on the tenth day with the passage of much blood. No organisms were found in the stools, but on the sixteenth day P. *trix* was discovered in the blood. After antimalarial treatment the temperature fell to normal and quick recovery from diarrhoea took place.

The examples quoted are only a few of many cases which indicate that the children's doctor in endemic area should be aware that enteritis in sucklings

and young children may result from malaria. In the treatment of such conditions the author recommends the parenteral use of drugs, because, according to him, the drugs may not be well absorbed in very young children, particularly when they are suffering from diarrhoea.

The toxic effects of malaria in sucklings are discussed in detail and mention is made of interference in carbohydrate metabolism during malaria. There is little in these sections which needs comment.

The effects of malaria on the central nervous system in children are most striking. These disturbances often appear suddenly in apparently healthy children, and the fate of the child is often settled in a matter of a few hours. Sometimes the development is slower. Diagnosis is often missed and differential diagnosis is difficult. The author gives a table of the various central nervous system complications which may develop, *viz* —

The Nervous Complications of Malaria in Children —

A *Coma prodromal stage*

- 1 Cephalalgic form (headache only)
- 2 General asthenia, apathy, feeling of illness, nausea, usually with headache, hypersensibility and hyperaesthesia, eventually vomiting

B *Coma*

- 3 Coma with slow onset
- 4 Fulminating coma (so-called "Sunstroke" or "Apoplexy")
- 5 Meningitis form (including Ophthalmoplegia)
- 6 Encephalo-meningitic form
- 7 Infantile toxic malaria
- 8 Typhoid-type malaria
- 9 Epileptic form (convulsion) with epileptiform onset merging into coma
- 10 Tetanic form

C *Lesions with a more or less subacute course*

- 11 Neuritic form
- 12 Hemiplegic form
- 13 Athetotic form
- 14 Amblyopia
- 15 Ophthalmoplegia (see also B5)
- 16 Neuropathic form
- 17 Psychoses

The tremendous importance of correct diagnosis is emphasized. Many interesting case histories are given, including a number illustrating what the author describes as "fulminating coma". An apparently healthy child playing in the streets develops severe cramps and deep coma. In hot countries this may often be mistaken for sunstroke, which, in fact, may be associated with it. The author stresses that in all cases where sunstroke is suspected, blood examination must be made. If such examination is impossible, treatment should be started without delay. He recommends quinine injections. As an example of this type of case he quotes the history of a child of seven years who became ill while playing at home. He fell down suddenly, became immediately unconscious, and was brought into the clinic at once by neighbours. On examination there were very severe clonic cramps of the extremities, trunk and face. The child was deeply unconscious, the pupils constricted and non-reactive to light. He was vomiting, the spleen was enlarged, the temperature 41°C, and the blood showed *falciparum* parasites. The cerebrospinal fluid was under high pressure, there was an increase of cells, a small increase in albumin (40 mgm per cent), and a considerable increase in sugar content (180 mgm per cent). After lumbar puncture, the cramps lessened in

intensity but coma persisted. Intravenous and intramuscular quinine injections were followed by rapid recovery.

The author stresses the point that the meningitic form of malaria coma is relatively common in children, and that therefore cases may easily be mistaken for meningococcal or tuberculous meningitis. He recommends lumbar puncture in such cases not only as a diagnostic procedure but also because the pressure is raised in most malarial cases and should be relieved. He discusses the relation of the blood and cerebrospinal fluid sugar concentrations. In 42 cases with nervous complications in malaria, 33 showed an increase in cerebrospinal fluid sugar.

Psychosis as a result of malarial infection is apparently less frequently met in children than in adults. Acute psychoses however do occur and may be present in the prodromal stages of the attack. Case histories are quoted.

Possibly one of the commonest effects of malaria in children is the production of some degree of anaemia. The colour index may be equal to slightly greater or less than one and the red blood cell picture shows general reduction of numbers, together with poikilocytosis, anisocytosis and polychromasia. Megalocytes may be present in acute malaria, and, according to the author (in contrast to most observers) normoblasts are rare, which he regards as an indication of severe damage to the haemopoietic system. Severe anaemia in children as the result of malaria is commoner in some regions than in others. In the author's polyclinic, among 4,200 cases, there were 113 with haemoglobin between 10 and 35 per cent.

The white blood cell picture depends on the degree and state of the infection. Leukopenia is characteristic in the acute stage.

The author recommends treating anaemia by treatment of the malaria plus the administration of liver preparations and extracts of iron and copper. In very severe cases blood transfusion may be necessary. In the newborn and young sucklings 50 to 100 cc. of blood should be given in very young children, 100 to 200 cc. in school children 200 to 400 cc.

Blackwater fever may occur as a complication in children, the signs and symptoms differing little in detail from the similar condition in adults.

Treatment of malaria in children is discussed in detail. Doses of quinine in sucklings from birth to two months 30 to 50 mgm. per day from three to twelve months, 50 to 100 mgm. per day. In young children of one to five years, 100 to 300 mgm. per day in school children of six to fourteen, 500 to 800 mgm. or as much as 1,000 mgm. per day. In general, the author reckons the quinine dosage as 100 mgm. per year of life. Child of eight for example, would have up to 800 mgm. in the day. Certain non-bitter compounds of quinine are recommended.

Atebrin should be given after food with plenty of fluid. The treatment should continue from five to seven days. Children up to the age of four may be given up to 100 mgm. per day. From four to eight, 200 mgm. over eight 300 mgm. The author has observed nervous changes, including general sleepiness in some sucklings taking atebrin and in one child of four years ataxia of the lower extremities and ulnar involvement with recovery after two months. Behaviour changes were observed in a child of nine years who was treated for six days with atebrin 300 mgm. per day. This child became disorientated and had hallucinations. He was unaware of his surroundings and any kind of understanding with him was impossible. He became apathetic, had to be forcibly fed, and was incontinent of urine and faeces. After four days he recovered.

The dosages of pamaquin mentioned are those given by Nocht. In the upper age groups these are rather higher than are usually given to adults in Britain. For example, between the ages of six to fifteen, 10 mgm. from

three to five times in the day are recommended. The author points out that toxic symptoms may possibly occur with these dosages. This is hardly surprising.

At the end of the book there are some quite useful illustrations showing various methods of protection against malaria by screening, and photographs of children suffering from malaria, illustrating enlargement of spleen, toxicity in sucklings, liver cirrhosis, typhoid malaria, meningitic and encephalitic malaria, etc.

B G Maegraith

ONABAMIRO, Sanya Dojo [B Sc (Manchester), FLS] **Why our Children Die The Causes, and Suggestions for Prevention of Infant Mortality in West Africa** With a Foreword by Lancelot HOGBEN pp vi+196 1949 London Methuen & Co, Ltd, 36, Essex Street, Strand, W C 2 [8s 6d]

That infant mortality rates are high in tropical Africa is widely known, but few people, European or African, even if they have lived their lives in Africa, realize the extent of the wastage and tragedy of infant and child deaths. Nor is it only ignorance of the facts that delays and retards measures for improvement. Many Africans, even among the well-educated, accept as inevitable the appalling conditions. The main aim of this little book, written by a Nigerian zoologist, is to bring home the facts of infant and child mortality to the rapidly increasing number of educated men and women in British West Africa and to awaken them to the realization that most of these deaths are avoidable and that measures for eradication of the main causes can and should be undertaken at once.

As is the case throughout most of tropical Africa the vital statistics available for the four British territories on the west coast are very incomplete. Maternal and infant mortality data are recorded in annual reports but refer only to a small proportion of the population, that of the large towns and such few rural areas as are served by a hospital or mission. Even these are very high and such scanty evidence from the rest of the countries as can be gathered together suggests that the overall infant mortality rate for such territories as Nigeria and the Gold Coast is probably not less than 40 per cent or more than six times as high as the rate in the United Kingdom.

After summarizing the available statistics the author turns to the causes of the high mortality rates. Among these he first deals with African methods of midwifery. Here the author has been unusually fortunate: there can be few scientists who have been present at deliveries carried out by village medicine-men. His description of what takes place on these occasions is fascinating and probably unique. The actual methods of delivery of normal cases, being mainly natural, are open to relatively little objection, but the complete inability to deal with even the minor deviations from normal leads to many fatal results, and the risks to the infant of infection and exposure, in the insanitary surroundings and during the handling by unnumbered friends and relatives, are tremendous.

The child's chances of survival are largely dependent upon the mother's health during pregnancy, and its own exposure to disease in its early months of life. In both respects the scales are heavily weighted against it. Many West African women bear children at far too early an age and, during pregnancy, live in great poverty in insanitary surroundings, doing most unsuitable work and exposed to a wide range of endemic diseases. Above all, malnutrition and undernutrition are widespread throughout whole populations. This has a particularly adverse effect during pregnancy, as not only are the requirements greater at that time, but in many areas customs and taboos limit the food of the expectant mother.

Similarly during its early struggles the infant has to contend with a host of adverse conditions. Water-borne diseases, insect borne diseases, skin and respiratory tract infections, and helminthic and protozoal infections all contribute their share to high infant mortality rates.

The longest chapter in the book is devoted, probably rightly to malnutrition as the most important single contributory factor to high infant and child death rates. The author describes in considerable detail the nature functions and sources of all the known vitamins and indicates how greater quantities of these nutrients might be included in African diets. Understanding of this chapter demands a much higher level of scientific knowledge than does the rest of the book, and it may be that it will lose some of its effect from being above the heads of many readers. It would have been better to treat the subject from the point of view of foods rather than of nutrients. Moreover there is lack of balance here in that many pages are devoted to consideration of the vitamins, whereas protein and mineral deficiencies are dismissed in a few brief paragraphs, and pure caloric undernutrition, still probably the most common dietary defect in Africa, receives no mention at all.

In his final chapter of conclusions and suggestions the author wastes little time in apportioning blame for the existing conditions, though he does point out that these conditions do little credit to British Colonial Governments. The ultimate solution of the problems lies in a many-sided attack upon poverty, disease and ignorance. Improvement will come through economic advancement, extended medical and maternity services, a wide programme of dietary legislation and by education at every level and by all available means.

There are many points of detail in this book that could be criticised, but they are unimportant compared with the urgency of its message and complete conviction conveyed by the author. It is only to be hoped that the book achieves the wide circulation and active attention it deserves. Nothing in it is more eloquent than the dedication. To my mother of whose eight children seven died in infancy.

Dean A. Smith

SOUTH PACIFIC BOARD OF HEALTH. A Guide to Pacific Island Diets.

[Compiled by J. C. R. BUCHANAN] pp. xiii+75 1947 Sova, F.J.

This little handbook was originally intended for the use of the student and graduates of the Central Medical School in Sova, but it is hoped that it will reach a far wider range of readers. Nurses, teachers, health sisters welfare workers, members of the public and all in the area who are able in any way to exert an influence for the better use of food will find it of the greatest value and interest.

The book opens with a chapter on general principles. This is written at a semi-popular level, is brief but adequate and avoids the major pitfalls of inaccuracy which often appear in the simple presentation of a complex subject.

The chapter on common Pacific Island foodstuffs contains much information and includes descriptions of methods of cooking and utilization as well as of the foods themselves. This information is made use of in the dietary scales which follow. They are sound, realistic rations made up of readily-available local foodstuffs based on food categories and covering the needs of a range of sex, age and activity groups. The book ends with a table of food values and a selected bibliography.

The food tables consist of a few slips which will, no doubt be corrected in the next edition (e.g. Sourrop Protein 0.1 gm. Fat 0.4 gm. carbohydrate 17 gm. calories () and there is some confusion in the calculation of values for vitamin A and carotene but these very minor criticisms should not be held to detract in any way from the value of the work. It is as good a popular book as any yet written on the local foodstuffs of an area.

SUMMARY OF RECENT ABSTRACTS*

VIII TYPHUS GROUP OF FEVERS

General

WEYER *et al* (p 1075) have examined rickettsiae by the electron microscope, and think that they resemble bacteria rather than viruses in structure and also in composition and behaviour. On the other hand, as a result of study of the action of enzymes on rickettsiae, CALLOT and VENDRELY (p 990) conclude that rickettsiae are intermediate in structure between bacteria and viruses.

CAMAIN (p 322) considers that the use of Machiavello's method, and hot Giemsa, is not a sure method of detecting rickettsiae.

*Proteus OX19 type Vectors, louse and flea**Louse typhus*

Epidemiology—MACCARTHY (p 696) notes the high louse-infestation rates found in people wishing to emigrate from Eire, and examined before doing so, and refers to two outbreaks of typhus in which infection was probably acquired by inhaling infected dust in which rickettsiae had remained virulent for 41 and 15 years respectively.

MORGAN *et al* (p 887) report two cases of Brill's disease, the form of louse-borne typhus which occurs as a recrudescence of a latent infection persisting indefinitely after an attack of that form of typhus. The patients migrated from Ireland to the United States 30 or more years ago.

In prisoners and others who returned to France in 1945, 167 cases of typhus were seen in Paris. BOYER (p 57) shows that there were only 15 cases secondary to these. Doctors and others in contact with repatriated persons were vaccinated with the Durand and Giroud vaccine. In spite of the influx of refugees during the war, and of the epidemic in Spain in 1941-42, there were relatively few cases in Portugal (DIAS, p 58). It was, however, proved that gypsies introduced it into the country from Spain.

Typhus in a hospital in Finland is described by HIRVONEN (p 776).

In the town of Jos, Northern Nigeria, louse infestation is heavy, and there was an outbreak of typhus in 1945. MONTGOMERY and BUDDEN (p 322) soon controlled the epidemic by dusting with DDT. Laboratory examinations made in connexion with this outbreak are reported by FINDLAY and ELMES (p 322), who isolated rickettsiae from patients and from lice. In a minority of tests

*The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin*, 1948, v 45. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.

some strains reacted more like murine than epidemic rickettsiae and the authors make the point that both these forms are known in West Africa, and that the tick-borne form also probably occurs there. In the third paper of the series (p. 324) Montgomery describes the clinical features observed which he thinks, were unlike those of classical typhus (but in comment MEGAW demurs at this conclusion).

JADIN (p. 325) has isolated orchitic strains of rickettsiae in two cases of the "red fever of the Congo" at Coetmansville. In each case the Weil-Felix reaction with *Proctus QX19* was positive but in two other cases this test was negative or positive at low titre only. JADIN and D'HOOGHE (p. 508) however claim to have isolated epidemic typhus rickettsiae from other patients in whom the diagnosis of red fever had been made. MEGAW comments that there is now no valid reason for retaining the name.

The epidemiological conditions at Lanchow in North-West China suggested that typhus is louse-borne, and this was corroborated by detailed examination of certain strains isolated (WAXO *et al.* p. 777).

Positive results to the Weil-Felix reaction were found (to a titre of 1 in 100 by FLOCH and CAMAR (p. 250) in a small proportion of sera submitted in French Guiana for the Widal test. They describe a case of murine typhus in man.

A complement fixation test in which *R. prowazeki* was used as antigen indicated that a quarter of the people in a group of villages in Colombia had been infected with typhus but MONTORA *et al.* (p. 419) point out that the antigen did not differentiate between the louse-borne and the flea-borne types though epidemiological conditions suggested the former.

Aetiology transmission.—RABINOWITZ (p. 896) has cultivated *R. prowazeki* in embryonated eggs killed by chilling on the third day of development.

CLARKE and FOX (p. 906) show that suspensions of *R. mooseri* and *R. prowazeki* cause haemolysis of red cells from rabbits and sheep but not from certain other animals. The degree of haemolytic activity (which is inhibited by homologous anti-serum) may provide an index of infectivity and the haemolytic factor may be identical with the rickettsial toxin.

By experiments on chick embryos infected with typhus rickettsiae and by using *p*-aminobenzoic acid and potassium cyanide GRIFF and PINKERTON (p. 508) have shown that rickettsial growth is inversely proportional to the respiratory rate of the host cells.

Desiccation of *R. prowazeki* in suspensions from the lungs of mice over calcium chloride *in vacuo* at 15°C. appears to reduce the number of viable rickettsiae compared with desiccation by the lyophile method at -10°C., when tested by the intradermal route but GIBSON and VARGAS (p. 1073) found little difference on intraperitoneal injection.

ANIGSTEIN *et al.* (p. 699) infiltrated the skin of guinea-pigs with anti-organ sera (prepared by inoculating rabbits with spleen or bone-marrow of guinea-pigs) and into the same area 2 hours later they injected material infective for typhus. Infection rarely occurred, but the authors do not claim that this procedure can be applied usefully in relation to human disease.

DELBORF and REYNES (p. 61) have investigated the course of typhus in guinea-pigs infected with *R. brucellae*.

KUTICA (p. 420) cultures lice in sterile conditions so that they can later be fed on patient suspected of typhus, and the diagnosis can be made by examination of their faeces.

Pathology.—CORREJO and ZITO (p. 591) have studied the histopathology of the small blood vessels in typhus and GURRINI (p. 591) that of the kidneys in the glomerulonephritis sometimes observed in typhus. HORTON *et al.* (p. 167) discusses the forms of gangrene found in typhus, and their pathology.

DE ROSNAY (p 166) states that the bone marrow in typhus shows an intense reticulo-endothelial response in the early stages, which may have diagnostic value. REVOL *et al* (p 590) have also studied the bone marrow in typhus. A study of the red cell sedimentation rate in typhus has been made by GOYTIA (p 324).

FRANK and MAY (p 988) investigated the protective power of human convalescent serum when mixed with rickettsiae of murine or classical typhus before inoculation into animals, the results were very variable. SIEGERT (p 988) refers to the antitoxic power of serum after typhus, in protecting mice from death after injection of rickettsial toxins. This power is much greater in persons recovered from the disease than in those who have been vaccinated.

Tests—With carefully prepared antigens of epidemic and murine typhus. PLOTZ *et al* (p 699) were able to show that the rickettsia-agglutination test in typhus was positive earlier than the complement-fixation test, and that by both tests it was possible to differentiate between epidemic and murine infections. The agglutination test gave more cross reactions than the complement-fixation test. Similar work on murine typhus was carried out by almost the same team, SCOVILLE *et al* (p 700), with similar results. The murine rickettsia-agglutination test was always positive after the 9th day, but the murine complement-fixation test with washed antigen was negative at 10–19 days in most cases, though with non-specific soluble antigens it became positive earlier.

JADIN and GIROUD (p 592) note that in an epidemic of typhus in Urundi, 18 of 23 sera agglutinated epidemic-typhus rickettsiae at much higher titres than murine rickettsiae. These authors (p 697) prefer the rickettsia-agglutination test to the complement-fixation test, and make the point that it clearly differentiates between epidemic and murine typhus during the 3rd and 4th days of the attack, and after the height of the attack, but less clearly in the intermediate stage or when the serum has been inactivated by heat or has long been stored.

GIROUD and LE GAC (p 1076) have done rickettsia-agglutination tests (with murine and epidemic rickettsiae) and Weil-Felix tests, on patients with boutonneuse fever, and conclude that there is an antigen common to epidemic typhus and boutonneuse fever.

SANDOR *et al* (pp 166, 986) have studied the relationship of anti-typhus agglutinins in infected animals, to the various euglobulin fractions of serum.

GIROUD *et al* (p 60) show that crushed and washed typhus tissues retain appreciable amounts of antigen, and that potent antigens in suspensions of infected animal lungs provoke a rise in rickettsia-agglutinin titre on injection into rabbits. GIROUD and CIACCIO (p 885) show that soluble antigens from the lungs of rabbits infected with *R. prowazeki* extracted with alcohol are rather more satisfactory than those extracted with saline solution or water.

BERGE (p 778) has used soluble antigens of *R. prowazeki* and *R. mooseri*, released by extraction with ether, for the complement fixation test. These antigens do not differentiate between the two types of typhus, but the test has a value for screening, and therefore for reducing the need for subsequent more refined tests, in diagnostic and survey work.

The addition of traces of egg yolk to suspensions of yolk sacs infected with various rickettsiae before treatment with ether gives antigens with enhanced complement-fixation titres (HOTTE and SHEPARD, p 248).

VAN DER SCHEER *et al* (p 60) show that although non-specific reactions with Wassermann-positive sera are given in complement-fixation tests in which yolk-sac rickettsial vaccines extracted with ether are used as antigens, they rarely occur if the vaccines are purified by shaking with benzene and concentrated by precipitation with sodium sulphate. By these tests Rocky

Moussain spotted fever can be distinguished from epidemic and murine typhus, but differentiation of the two last was not easy.

BARKENFELD and DROCKERT (p. 591) prefer fresh serum to serum inactivated by heat in the complement-fixation test for typhus.

GIROUD and JUDÉ (p. 167) quote evidence which indicates that there are specific differences between the agglutinins for *Proteus* and rickettsiae. GUÉ (p. 887) shows that agglutinins against *Proteus* O119 are very variable in their resistance to heating at 50°C. for one hour. Thermostability is not valid in differentiating agglutinins derived from infections with *Proteus* from those arising as a result of typhus. HINDSFELD (p. 697) has isolated strains of *Proteus* V from blood, urine or post-mortem material of patients with typhus.

Clinical findings.—SCHMIEDER (p. 887) has studied the encephalogram in patients showing after-effects of typhus. It has some diagnostic value.

BERCEANU and CUCUREANU (p. 688) noted that nervous symptoms dominated the clinical picture in 141 of 230 cases of typhus in Bucharest and that in all 230 there was some degree of cellular reaction in the cerebrospinal fluid. LEMKE (p. 62) gives details of some of the late effects of typhus especially in relation to the nervous system and the heart.

HORTOPANT (p. 608) relates the comparatively low mortality in typhus of recent years to the improvement which has taken place in the standard of life in European countries, and he comments on the relatively high mortality in people over 40. DIGNAZZIO (p. 888) refers to the recent dramatic fall in the case-fatality rate of typhus in Ethiopia. This is probably the result of improvement in hygienic conditions, louse control and the use of vaccines.

T. naturalis.—Chloromycetin is described by EHRLICH *et al.* (p. 779) and its great value in prevention and treatment of rickettsial infections of chick embryos and mice is reported by SMADEL and JACKSON (p. 779). In human typhus its remarkable value was shown on a small scale in Colombia by PAYNE *et al.* (p. 779) who gave it by mouth or intravenously. There were no toxic effects. LAY, SMADEL and CROCKER (p. 1076) administered chloromycetin by mouth to normal persons in various doses and noted the blood levels. Excretion is rapid and no ill effects were experienced. SMADEL, LAY and VARELA (p. 1077) used it in several cases of typhus in Mexico, with good effect. They suggest an initial dose of 40 mgm. per kilo body weight, followed by a daily dose of 35 mgm. per kilo in divided doses at intervals of 2 hours, until improvement occurs, then a daily dose of 20 mgm. per kilo (divided, every 4 hours) until the 14th day after onset.

GIROUD (p. 420) has shown that streptomycin has a definite effect on typhus rickettsiae when tested intradermally, but much less when mice infected intranasally are treated with it. Certain acetone compounds were found by SMADEL *et al.* (p. 168) to have rickettsiostatic effects in infected chick embryos, but the margin of safety was low. Later (p. 321) the authors showed that streptomycin inhibits the rickettsiae of typhus and Rocky Mountain fever, but not of tsutsugamushi disease in the same conditions, and that nitroacryline and β -aminobenzoic acid have some synergic action with streptomycin.

REXER (p. 779) has treated large number of cases of typhus. He distrusts many of the drugs which have been advocated by others, but he has had success by administering cardiovascular tonics and sedative drugs, only when there are definite indication for them. Convalescent blood is useful (but the author gives little relevant information) only when given up to the third day of illness.

Trials of 17 methods of treatment of typhus were made during 8 years by FERRO-LUZZI and FERRO-LUZZI (p. 719) in Entrea. These did not include the use of β -aminobenzoic acid. The only one which seemed to give good results was the administration of asparin, but in comment MCGAW suggests that the

controls used do not satisfy the requirements necessary for unequivocal acceptance of the value of this treatment

Vaccination —BIELING and OELRICHS (p 886) use the intradermal injection of minute quantities of yolk-sac growth of typhus rickettsiae, as a means of measuring the antigenic potency of the strains With large doses (and also with killed suspensions) this method provides an appreciable degree of immunity against homologous strains within 7 days The potency of vaccines can be measured by the quantity of immune serum needed to prevent the Giroud reaction

In 60 laboratory workers constantly exposed to typhus infection, and protected by the Durand-Giroud vaccine, 12 suffered from mild attacks and 4 from inapparent attacks, all diagnosed by Giroud's intradermal test and rickettsia-agglutination tests (CHEVÉ *et al*, p 249)

RUIZ CASTAÑEDA (p 592) has elaborated a method for purifying and concentrating suspensions of epidemic- and murine-typhus rickettsiae for the preparation of vaccine He prefers the vaccine containing both types, partly because the murine form may be transmitted from man to man by lice, in epidemic fashion, and he advises that a course of 5 doses should be given, at weekly intervals ORRIZ MARIOTTE (p 1077) reports a test of the Castañeda bivalent vaccine in Mexico in 1942-43 There was apparently some benefit, but the numbers are small Later an improved vaccine gave better results

FRANKE (p 777) observed the Weil-Felix titre after inoculation with 3 doses of various vaccines, the titre rose moderately in most cases, but soon declined

Control —By using 10 per cent DDT in talc or pyrophyllite for body lice, and 5 per cent phenyl cellosolve for head lice, on several occasions, MONTORA and OSEJO (p 989) reduced the infestation rates in a Mexican village to less than 5 per cent for several months In another village, and with only one application, the rates were much reduced, but increased again after some months

Flea typhus

DUNN (p 781) reports a case, apparently of murine typhus, in a London dock worker much exposed to fleas while unloading cargoes from abroad

SAVOOR *et al* (p 888) have investigated cases of typhus in Bombay City, and conclude that the clinical and epidemiological features are consistent with the diagnosis of flea-borne typhus They describe a modification of the rapid slide test with *Proteus OX19* They (p 1077) have isolated and studied strains identified as *R mooseri* in Bombay They report their study of the characteristics of these strains, which are of lower virulence than the Wilmington strain

RAYNAL (p 59) once more argues his theory that in Shanghai the rickettsiae of murine typhus are spread by fleas from rats to man, and thence from man to man by lice He names the common rats and their fleas But in addition, during the war, true louse-borne typhus was introduced from outside, and resulted in epidemics Murine typhus has been detected in cats in Shanghai, and RAYNAL (p 251) refers to the possible danger of infected cats to man

Most of the 184 cases of typhus in two hospitals in Chengtu appear to have been of the flea-borne type (LIU *et al*, p 325)

ESKEY and HEMPHILL (p 990) show that murine typhus in the United States is found chiefly in the south The months of highest prevalence are July-September and the numbers of cases reported have increased almost every year since 1913 perhaps because the disease is now more generally recognized Typhus of murine origin is spread uniformly in Florida, U S A, and the rural population is nearly as heavily infected as the urban, RICKARD and RILEY (p 780) estimate that two-thirds of the patients reported in 1944-1946 acquired

infection in their homes—most of the others were probably infected at their places of business especially those concerned with food handling. In Texas IRONS *et al.* (p. 780) showed that almost all urban establishments examined harboured rats with positive complement-fixation tests for typhus and that 7 per cent of farms examined also harboured such rats. The disease is evidently widespread in rats and these rural areas must be included in control schemes. DAVIS (p. 888) shows that the complement fixation test was positive in 34.7 per cent of *R. rattus* and 51.4 per cent in *R. norvegicus* in a town of Texas. Rats from grain mills were more frequently positive than others.

COLE and KOEPKE (p. 41) discuss the interpretation of the data of rodent ectoparasite surveys and give in detail the results of surveys in Florida, Georgia and Alabama. The long paper contains analyses of large surveys of rats, their fleas and mites and for these the original should be consulted. The work has a bearing on flea-borne typhus.

CALFRO (p. 702) reports an outbreak of typhus of murine origin in Panama city. The patients had all worked in a food store.

A long description of the characters of a strain of murine typhus rickettsia given by HALYRANU and CONSTANTINESCU (p. 1078).

WEI and WEI (p. 62) have infected silkworm pupae with murine typhus rickettsiae. VARELA and MAZZOTTI (p. 251) show that the armadillo and the field rat are susceptible to murine typhus.

Rats become more susceptible to typhus than normal if they are given a diet low in protein, or in certain vitamins of the B group (pantothenic acid, riboflavin, thiamin). FITZPATRICK (p. 781) shows that reduction of the amount of certain other substances does not have the same effect.

NYKA (p. 325) reports a close study of the histological changes in the lungs of rats inoculated by the nasal route with murine rickettsiae and of the development of the rickettsiae themselves.

In a typhus control programme in the southern United States (relating to flea-borne typhus of murine origin) the method adopted was to apply 10 per cent DDT to rat runs, burrows and harbourages. WILFY (p. 423) shows that there was a very considerable reduction of human cases in the dusted areas, compared with the incidence in former years, and that the numbers of *Y. cheopis* have greatly diminished.

Proteins OVA type Vector mite

The War Office has reproduced, in mimeograph form, a series of reports by ARDY and his colleagues (p. 62) on investigations on scrub typhus in south-east Asia. The work was done largely at the Scrub-Typhus Research Laboratory Imphal, in 1945-46. There are papers on the outbreak which occurred and on the work of the Medical Research Council Scrub-Typhus Commission (the latter by Dr R. LEWTHWAITE). The second part consists entirely of illustrations but the third part comprises 22 appendices, of which several by ARDY PARKER, HALRA, RADFORD and BROWNING deal with epidemiological subjects, including accounts of outbreaks in India, Ceylon and the Maldives Islands. Some of these have already been noticed in this Bulletin. Four appendices deal with subjects relating to the various mites, especially *Trombicula deliensis* which may be a variant of *T. akamushi*. Several appendices refer to bacteriological and serological aspects of the subject and a few to the survey methods adopted. It is not possible to condense these important papers further; they cover a very large field, and form a most important record. The original abstracts give much information on their contents.

In a review of knowledge of scrub typhus gained during the war FENN (p. 991) refers to the fact that it might have seriously interfered with the campaign had not quick and effective measures of control been devised. He

points out that larval mites do not ingest blood, but only lymph and tissue fluids, and that they do not remain attached to animal hosts for more than 3-4 days. The chief reservoirs of infection are the mites themselves (as also are the ticks of tick-borne typhus), and the vertebrate hosts are only transitory reservoirs [but see FOX, below]. There is evidence of much difference in virulence in different areas, case-fatality rates varied from 0.6 to 35.3 per cent in different outbreaks.

SAYERS and HILL (p. 593) report on the fevers of the typhus group in South-East Asia Command during 1941-44. There were about 5,500 cases, of which more than 90 per cent were of mite-borne typhus, and a small proportion of tick-borne or possibly flea-borne disease.

SAVOOR & DAS MENON (p. 781) diagnosed four cases of scrub typhus in persons who had not been away from Bombay City for four weeks before the attack. *R. orientalis* was isolated from one. Infection was probably acquired from mite-infested coarse vegetation, or from the handling of vegetables. SOMAN (p. 701) reports on the Weil-Felix reaction in Bombay, where the response is usually of the *Proteus* OX19 type, though cases of OXK reaction are seen. In comment, MEGAW points out that the tick-borne disease may give the OX19 response. SOMAN and DAS MENON (p. 890) also report cases in Bombay in which the reaction was of OXK type, and the rickettsiae of *R. orientalis* type.

Liu *et al.* (p. 1079) report 6 cases of the *Proteus* OXK type from north-west China. Previous records of this form in China have been rare.

RIGHTS and SMADEL (p. 702) have shown that resistance provoked by various strains of *R. orientalis* is not necessarily valid for heterologous strains.

The Moroccan rodent *Meriones shawi* is susceptible to intraperitoneal inoculation of *R. orientalis* (NOURI, p. 889).

DAVIS *et al.* (p. 70) refer to the recovery of 85 strains of *R. orientalis* in Assam and Burma, and to the demonstration of the actual presence of rickettsiae in the tissues of a rat experimentally infected by laboratory-reared offspring of infected mites. FOX (p. 889) has recovered *R. orientalis* from the tissues of infected Swiss mice as long as 610 days after experimental infection, and in cotton rats up to 269 days. The blood was also positive, but for shorter periods. He comments on the significance of these findings in relation to the rodent reservoir of tsutsugamushi disease.

KALRA (p. 70) has observed intracellular inclusion bodies in association with intraperitoneal infection of mice with *R. orientalis*.

The incubation period of tsutsugamushi disease in North Queensland is about 13 ± 2 days. SOUTHCOFF (p. 251) noted that most of the eschars were on exposed parts of the body, which suggests that dibutyl phthalate should be used in prevention. There is evidence that birds are important in spreading the mites, and lizards in maintaining them.

An account of scrub typhus in 68 patients in North Burma is given by REDDI (p. 71); he diagnosed the disease only if the *Proteus* OXK titre rose to 1 in 320, and he notes that in the first week most of the patients showed a positive Widal reaction at 1 in 160 or 1 in 320.

FOX and PETERSON (p. 592) have found that certain thionine dyes have a bacteriostatic action in infections of mice with *R. orientalis* and *R. mooseri*.

SANDER and MORTON (p. 252) have found that a mixture of equal parts of benzyl benzoate and dibutyl phthalate is almost as good as, and rather more persistent than, benzyl benzoate alone, for the impregnation of clothing to protect against mites. Benzyl benzoate itself is rather more effective than dibutyl phthalate. HORTON *et al.* (p. 593) report toxic effects from benzene hexachloride impregnated in garments as a protection against mites to such an extent that it can be used safely only in such low concentrations as to

eliminate any advantages as an insecticide it might possess over other compounds.

Benzene hexachloride at the rate of 6 lb. per acre is lethal to mites for three weeks or more. LIXDUSKA and MORTON (p. 326) have used it from aircraft or applied by hand, in trial plots of land. The object was to find a means of preventing scrub typhus by destroying the vectors before the land is used for camping.

Indeterminate type Vector tick

BETTINARDI (p. 423) has written a critical summary of the extensive literature of the tick-borne typhus of the Mediterranean. PARTILOS (p. 377) reports a case which he diagnosed as boutonneuse fever in Cyprus. COMBESCU (p. 1047) has isolated rickettsiae from *R. sanguineus* in Rumania where boutonneuse fever occurred.

FINDLAY and ARCHER (p. 782) report three cases diagnosed as tick-borne typhus in European soldiers in West Africa. Serological tests indicated affinity with South African tick typhus but not with house-borne or flea-borne typhus. DICK and LEWIS (p. 328) describe a rickettsial disease in troops and prisoners of war in East Africa, which they think was transmitted by ticks (*Rh. picephalus simus* and *Hemaphysalis leachi*). Similar cases were being reported from many areas at the same time. STOKES (p. 800) has isolated strains of epidemic and murine typhus rickettsiae in Eritrea. He has also isolated strains from the ticks *Rhipicephalus sanguineus* and *R. appendiculatus*. He describes an outbreak of tick typhus which is closely allied to boutonneuse fever. Some of the dogs in Asmara give Weil-Felix reaction of OX19 or OX4 type at high titres (STOKES and SOLIMAR, p. 800).

STREETLY *et al.* (p. 831) report tick typhus from Queensland. In some of the cases the Weil-Felix reaction was positive in high titre to *Proteus* OX19.

In Mexico epidemic and murine typhus, and Rocky Mountain spotted fever are known to occur. BUSTAMANTE and VARELA (p. 165) note that *Rh. picephalus sanguineus* and *Am. m. mexicanus* are the vectors of spotted fever. These authors (p. 232) produced typical Rocky Mountain spotted fever in guinea-pigs inoculated with material from *R. sanguineus* collected from river parts of Mexico.

KELSEY and HARBELL (p. 1079) discuss the treatment of Rocky Mountain spotted fever in children. There is an indication that hyperimmune rabbit serum may be useful if given during the first 3 days. With a dose of 0.33 to 0.5 gm. *p*-aminobenzoic acid per lb. body weight in children suffering from Rocky Mountain spotted fever. TICKNOR *et al.* (p. 328) maintained blood level of 15-40 mcgm. per cent. This treatment was continued for about 7 days, and the results indicated beneficial action in 6 of 8 cases so treated. For the treatment of Rocky Mountain spotted fever RAVENEL (p. 168) has used *p*-aminobenzoic acid in doses 1.05 gm. per pound of body weight for large children, or more for small children. Give blood concentration 130-60 mcgm. per 100 cc.

Serological studies undertaken two years after an outbreak of what was diagnosed as atypical pneumonia have shown that the patient reacted strongly to the complement-fixation test for Q fever. LA GRILE and DIXON (p. 164) therefore think that the outbreak (in Italy in 1945) was Q fever, which was responsible for a number of outbreaks about that time.

COMBESCU *et al.* (p. 104) have identified rickettsial disease in man in Rumania which was probably Q fever. LAYZ and GOURIN (p. 841) report Q fever from Turkey.

Q fever

GSELL (p 327) has established the occurrence of Q fever in Switzerland. Although the reservoir and the mode of transmission could not be determined, there seems to be an association with cattle and the possibility that infection may be acquired by inhalation of infected dust. An outbreak of Q fever, diagnosed retrospectively by serological tests, occurred in men in Switzerland engaged in unpacking heavy goods from America. WEGMANN (p 782) thinks that this was due to inhalation of infected dust from the packing straw.

An outbreak of Q fever took place in a Chicago slaughtering establishment. SHEPARD (p 71) points out that the patients handled the freshly killed animals, and as there was no indication of transmission by arthropods, he thinks that infection was probably acquired by inhalation of infected droplets. SHEPARD and HUEBNER (p 992) discuss the epidemiology of Q fever (often diagnosed originally as atypical pneumonia) in Los Angeles County. It occurs in cattle, and in people associated with them, *R burnetii* has been found in raw milk. There is no evidence of tick transmission to man. Many cases of Q fever in California were in patients who had close contact with dairies, and 10-20 per cent of the cattle gave positive complement-fixation tests for Q fever. HUEBNER *et al* (p 509) infected guineapigs by injecting pooled milk, though none of the cows giving the milk was ill. Although there is no definite incrimination of milk in human cases, it is possible that it may be a source of infection by some mode yet to be determined.

STRAUSS and SULKIN (p 783) have found positive complement-fixation tests for Q fever in meat-handlers in Texas, they are probably the result of unrecognized attacks of Q fever. The same authors (p 783) note that the complement-fixing antibodies tend to persist for many months after clinical attacks of the disease.

EKLUND *et al* (p 71) describe a case of Q fever probably contracted by exposure to ticks in nature in Montana, perhaps through crushing them against the skin.

BLANC *et al* (p 892) used Q fever therapeutically in cases of mental disease. When infected guineapig material was injected intramuscularly a short fever resulted, but injection of infected ticks caused a longer spell of fever. Intradermal injection gave a local reaction, and very slight fever (in two patients out of 10). Nasal instillation also gave slight fever except in two who inhaled heavy suspensions, they, and also two attendants who wore masks, developed pulmonary manifestations.

Streptomycin is rickettsiostatic, and HUEBNER *et al* (p 594) have found that it is effective in treatment of guineapigs infected with *R burnetii*, but the treatment was started much earlier than would be possible in human Q fever. Successful treatment of Q fever with streptomycin is reported by ROSOVE *et al* (p 892).

SMADEL *et al* (p 424) have prepared yolk-sac vaccines of the rickettsia of Q fever, but have had no opportunity to test them in man.

Trench fever

ASCHENBRENNER (p 783) reviews the literature on trench fever.

BIELING and OELRICHS (p 893) found that Russian prisoners of war employed as donors of blood to clean, laboratory-bred lice infected them with *R quintana*, although the prisoners had not been exposed to infection for 2-3 years. The infectivity was not associated with recrudescence of symptoms of the disease. The same authors (p 892) show that serum of human convalescents from trench fever inhibits *R quintana*, and that this can form the basis for a Giroud test.

Rickettsialpox

The initial lesion of rickettsialpox resembles that of scrub typhus and the rash is similar to that of other rickettsial diseases, except that vesicles occur (Duganov, p. 703)

An account of rickettsialpox has been written by GREENBERG and PRILLITZ (p. 71)

Charles Wilson

MALARIA

DE OLIVEIRA, C. G. & FREIRE, F. Jr. Uma epidemia de malária inoculada. [An Epidemic of Inoculated Malaria.] Reprinted from *Bol. Clin. Hosp. Cruz Lisboa*, 1948, v. 1, No. 4, 32 pp. (20 refs.) English summary

This is the report of a thorough investigation of a remarkable outbreak of *P. falciparum* malaria in Lisbon

In February and March 1946 two patients were admitted to hospital apparently suffering from malignant jaundice consequent upon neosalvarsan treatment of the syphilis from which they were suffering. Investigation showed that they were both suffering from *P. falciparum* malaria—both had anaemia and jaundice and one had cerebral symptoms. Two weeks later a third similar case was admitted. None of the three men had ever left Lisbon. *P. falciparum* malaria is not indigenous in Lisbon. The three men had all been undergoing treatment for syphilis in the same out-patient department.

One hundred and eighty-nine patients out of the 297 who had attended the venereal disease clinic during December and January were traced and examined. Twenty-five further *P. falciparum* infections were discovered. Thus there were 28 cases in all—six patients died.

The source of the infection appears to have been the regurgitation of blood into the syringe during the injection of neosalvarsamine into a sailor who had contracted both malaria and syphilis in Portuguese Guinea in the previous September. Thus the stock solution of the drug in use on that day became contaminated. This may have happened on two occasions—December 10th and January 17th.

ZOLTAI, A. A malária helyzet alakulása Magyarországon és a vértelen lehetőségei. [Malaria in Hungary and its Prevention.] *Véprezési közp.* Budapest, 1949, Mar 1, v. 30, No. 9, 281-7, 3 figs., 14 refs. French summary, p. 304

For many years malaria in Hungary had become a *maladie acclimatée* but its exact distribution was not worked out until the beginning of the present century. Special studies were undertaken by the parasitology department of the Hungarian Institute of Public Health from 1900 onward.

Before the last war there were only two epidemic foci in the north-east and south-west respectively, in their departments malaria where it existed at all, was only sporadic. The vectors are *Anopheles maculipes*, *A. stephensi*, *A. hyrcanus*, *A. messeae* and *A. foveatus*.

From 1933 to 1936 the number of cases notified annually had not exceeded 2,000. In the next five years the yearly average was about 5,000 and in 1941 it exceeded 6,000. The limit of malarial morbidity was reached in 1943 when 8,700 cases were reported. The author believes however that the number of cases notified represents only about one-tenth of the real total which he puts at 80,000 to 100,000 per year. Most of the infections are caused by *P. m.* and about 10 per cent by *P. falciparum*.

The direct mortality caused by malaria in Hungary is minimal. The principal importance of the disease is that it reduces general resistance and it has serious economic consequences in taking people away from their agricultural work during the summer.

After the war years of 1944-45, the malaria position in Hungary underwent a fundamental change. As a result of large-scale movements of troops and civilians, indigenous strains became widely diffused and new strains were introduced from outside. A large number of new foci were created and malaria appeared in many districts where it had not been known before or where it had been very limited. These new foci now accounted for about half the cases notified although previously the majority of cases had been reported in the two original foci referred to above.

These new conditions aggravated the serious economic consequences and antimalarial work was intensified. Besides free drugs distributed by the Institute and the extension of general control work on breeding grounds and water sources, experiences with DDT in 1947 have promised excellent results.

The distribution of malaria in Hungary is shown in two maps, a chart and a table.

H J O D Burke-Gaffney

MALMEJAC, R. Rapport sur l'épidémie de paludisme sévissant en 1946 dans le département d'Oran [Epidemic of Malaria in 1946 in the Department of Oran] *Algérie Med* 1947 Mar No 3, 259-63

A very severe outbreak of malaria occurred in the Department of Oran in 1946 more especially in the east and south-east. The previous three years had been dry and there had been a steady regression of malaria incidence. Insufficient treatment of cases, insufficiency of gametocidal drugs and the arrival in the Department of infected workers from Morocco ensured widespread sources of infection. Antimalarial measures were altogether inadequate, abundant spring rains caused a multiplicity of anopheline breeding places. The susceptible population was increased by the arrival of nomads from the high plateaux in large numbers. The resistance of the indigenous population had been weakened by successive epidemics of typhus and relapsing fevers.

Pernicious forms of malaria were unusually prevalent and the fatality rate was high. *P. vivax* and *P. falciparum* infections were both numerous, the latter appearing in September. Pernicious attacks of *P. vivax* malaria were commonly seen.

The author concludes with an urgent plea for the expansion and intensification of antimalarial work in the Department.

SCHWETZ J, BAUMANN H & FORT M. Contribution à l'étude du paludisme endémique dans le district du Kwango (Troisième note) [Contribution to the Study of Endemic Malaria in the Kwango District] *Ann Soc Belge de Med Trop* 1948 Dec 31 v 28 No 4 421-8

The authors report the results of the examination of thick drops and smears of blood from 167 children under two years of age living in villages near Feshi in the Kwango District of the Belgian Congo. Malaria has been less studied in this District than in others: a previous report was published in 1938 [this *Bulletin* 1939 v 36 778]. Feshi lies to the east of the area previously studied.

Malaria parasites were found in 53.2 per cent of these children under two years of age. *P. malariae* was found in 14 children, in association with *P. falciparum* in all cases but one. *P. vivax* was not found. Gametocytes of *P. malariae* were noted in 14 and crescents in 38 films. For the most part the parasite densities were not high.

Norman White

The cessation of fever accompanied by a drop in the number of parasites in the third week of the disease is regarded as the first sign of acquired immunity. The subsequent invasion of the reticulocytes is said to represent a reaction on the part of the parasites against the defence forces of the host, affording protection which enables them again to increase in numbers and bring about a new febrile paroxysm.

OWOBI, N. Observations on the Nocturnal Activities of the Anopheline Mosquitoes in Taiwan. I. Preliminary Report. *Acta Soc. Trop. Taihoku*. 1949, v 4 No. 1, 2, 59-67 2 pls. [11 refs.] (Summary taken from *Rev. Applied Entom.* Ser. B. 1949 Mar v 37 Pt. 3 38-9)

An account is given of studies carried out in 1939-40 on the nocturnal activities of Anopheline mosquitoes in a village in Formosa situated at the foot of the mountains, 500 ft above sea level. There were irrigated rice-fields and streams of running water in the neighbourhood and the people kept cattle, pigs and poultry. A bait trap of mosquito nets of the type described by Gater was used in the studies. A man occupied it from sunset onwards and collections were made every hour or two hours by means of a chloroform tube and an electric hand lamp. The observations were made on nine occasions, covering every season except spring, the trap being indoors on rainy nights and outdoors in fine weather. The mosquitoes were comparatively inactive when it was cold, rainy or cloudy. Results are shown in tables. Considerable numbers of mosquitoes entered the trap throughout the night in July whereas their activity decreased considerably after midnight in October. This was probably on account of the higher temperature in July as well as an hour's difference in the time of sunset. The species could be roughly divided into three groups. The first, comprising *Anopheles maculatus* Theo., *A. annularis* Wulp., *A. hyrcanus* var. *sinensis* Wied. and possibly *A. tricoloratus* Theo. began to enter the trap just after sunset, their numbers reached a peak in 3 hours, diminishing gradually until midnight and very rapidly thereafter. The second, consisting of *A. m. m.* Theo., and possibly *A. splendidus* Koide, showed increased activity about midnight and the third, comprising *A. pyreticus* or *cardioides* Koide, maintained sporadic activity through the night showing no definite pattern. Two females of *A. fulvipes* Theo. were also taken. *A. annularis* was by far the most abundant species and *A. m. m.* and *A. maculatus* were next in order of frequency. The total numbers taken being 2,151, 184 and 179 respectively. *A. m. m.* has been considered the principal vector of malaria on the island, followed by *A. maculatus* but in view of its numerical predominance the author considers that *A. m. m.* should be taken into account. Notes are also given on the results of collections of larvae from streams and other water near the village. *A. annularis* and *A. maculatus* were most frequently taken and larvae were also found of *A. fulvipes*, *A. austriacus* var. *bengalensis* Puri, and *A. indus* Giles, species that were not attracted to man, and of *A. hyrcanus* var. *sinensis* and one each of *A. punctatus* and *A. m. m.*

PECK, C. H. Pupae of the Neartic Anopheline Mosquitoes North of Mexico. *J. Nat. Hist. Museum Soc.* 1949 Mar. N. S. 1 50 figs 14 pls. 16 refs.

HARRIS, R. L. Universal Serologic Reaction with Lipid Antigens. V. In Malaria. *Amer. J. Cl. Path.* 1949 May 19 No. 5 414-15, 4 figs. Summary appears also in *Bullet. J. Hygiene*.

For the study of the universal reaction in malaria nine volunteers were inoculated with *Plasmodium vivax* and their sera were tested before inoculation.

and at various periods after inoculation. In one case, which was fairly typical of all, the results were as follows — (1) before inoculation limited precipitation in Zone I especially after 4 and 24 hours' incubation at 5°C, none in Zone II slight in Zone III after 4 hours and moderate after 24 hours, (2) 15 days after inoculation (when fever was subsiding and parasites becoming fewer) results much the same as in (1), (3) 29 days after inoculation considerable precipitation without incubation and further precipitation after 4 and 24 hours, (4) 2 months after inoculation, precipitation much decreased, (5) 4 months after inoculation, results similar to (1). Thus the malarial reaction occurred approximately one month after inoculation, 20 days after the beginning of the fever and about a fortnight after its subsidence the reaction tended to return to normal after about 2 months. It is not suggested that the above results have any practical application but they may be compared with those obtained in certain other diseases.

Dr. GRAM W. Over het recidiveren van malaria (Concerning Malaria Relapses *Nederl Tijdschr v Geneesk* 1949, June 4, v 93 (ii), No 23, 1849-60) English summary

In a prisoner of war camp in Batavia there were collected in the course of three years 651 cases of malaria. The disease did not occur normally in that area so that it was possible to watch relapses without the complication of new infections. There were three main groups —

1. The Timor group consisting mainly of incompletely treated Australian troops. They mostly had benign tertian infections.

2. The Flores group consisting of Dutch troops very heavily infected, many with mixed benign tertian and subtertian infections but mostly the former.

3. The remainder — a very varied group.

These patients were carefully watched. Most of the subtertian relapses took place within four weeks and there were none after nine weeks. Of the benign tertian relapses the greatest number 72 per cent, occurred within a month of the last day of treatment, 93 per cent occurred within two months. After two months the number of relapses fell steeply a fact to be borne in mind in assessing therapeutic and prophylactic measures. The peak of relapses occurred in the third week and the peak observed at seven months by James was not seen in this series.

A number of patients were followed up for many months some up to three years. Of these 40 had one 20 two 7 three 8 four 6 five 2 nine and 1 twelve relapses. A series of relapses could terminate quite suddenly or the interval could gradually increase till they ended or in some cases malaria parasites persisted in the blood without causing any clinical manifestations.

No patient continued to have parasites in his blood or to relapse for more than a year and a half.

Among the 85 subtertian cases there were six deaths but many fewer relapses than among the benign tertian cases.

Therapeutic material was very scarce but in spite of the difficulties controlled trials were carried out.

The first trials were directed towards economy in quinine. The original dose of 1.2 g. per day for seven days was reduced to 1.2 g. for five days (benign tertian cases only) with a decrease in the relapse rate. A few cases were treated with 1.2 g. for six days only. The small dose was apparently quite successful.

Subsequently the three forms of treatment were used on patients taken in rotation.

1. Mefenamic acid — 100 mgm three times daily for five days.

2. Quinine — 1.2 g. daily for five days.

3. Quinine as above immediately followed by plasmoquine 20 mgm. three times daily for five days.

The results from atebria were apparently the worst as judged by relapses, but there were only 18 cases drawn from the most heavily infected group supplies ran short after these had been treated. There was no statistically significant difference between the relapse rates of the three groups. The only advantage was apparently with the group given plasmoquine none of whom had more than four relapses.

RAYNAUD R. MINICONI P & CHEVROT L. Les états méningés du paludisme [Meningeal Conditions in Malaria.] *Algérie Méd* 1947 Mar No. 7, 15-21 16 refs.]

Three groups of meningeal manifestations can be distinguished in malaria infections: (1) meningeal reaction without clinical symptoms; (2) meningeitis complicating a more or less typical attack of malaria; (3) malarial meningitis in which the meningeal symptoms mask completely the basic malarial infection. The recognition of the first group depends upon an examination of the cerebrospinal fluid which shows a more or less marked lymphocytosis. This is of frequent occurrence in acute attacks of malaria. It may account for severe headaches, neuralgias, neuritis and paralysis of cranial nerves that are listed among the complications of malaria.

In the second group the involvement of the meninges has objective signs, rigidity of the neck and Kernig's sign, with lymphocytosis and increased albumin in the cerebrospinal fluid. These meningeal signs are superimposed on more or less typical symptoms of malaria.

Malaria meningitis is much rarer. Here meningeal symptoms are alone in evidence. The sudden onset and the absence of all the usual symptoms of malaria make the diagnosis extremely difficult. It is only in malarious countries that one would consider the possibility of a malarial infection. Lumbar puncture may reveal a normal cerebrospinal fluid in the early stages. Later the fluid may become opaque with a predominance of polymorphonuclear leucocytes. In the blood *P. falciparum* is almost always in evidence. In countries in which relapsing fever occurs the differential diagnosis may be further complicated as attack of relapsing fever may be ushered in with meningeal symptoms.

The authors describe cases illustrative of each of these three groups of meningeal manifestations in malaria.

Verma H. 412

RAYNAUD R. MINICONI P & CHEVROT L. Un cas de méningite palustre [A Case of Malarial Meningitis.] *Algérie Méd* 1947 Mar No. 3 233-5

A woman aged 33 after a few days of malaise, loss of appetite and slight fever suddenly lost consciousness and was admitted to hospital. She presented psychic disturbance which was attributed to alcoholism. Her temperature was 38°C. The following day she was found to be in a state of complete coma with a temperature of 41°. She presented a typical meningeal syndrome: muscular hypertony, rigidity of the neck and Kernig's and Brudzinko signs. The tendon reflexes were active, the light reflexion of the pupils was normal. Lumbar puncture showed a clear cerebrospinal fluid. The signs of meningitis were so unequivocal that intramuscular injection of penicillin and Salicylénol alternately were commenced without delay. The temperature fell but the nervous symptoms were aggravated. The following day the laboratory reported the presence of *P. falciparum* in the blood. Quinine treatment procured a rapid recovery though the psychic disturbance persisted for three or four days.

BENHAMOU, E, ALBOU & LEONARDON Les facteurs de pronostic dans l'accès pernicieux [Factors of Prognostic Significance in Pernicious Attacks of Malaria] *Algérie Méd* 1947, Mar, No 3, 238-45

A study of 55 cases of pernicious *P. falciparum* malaria have led the authors to the conclusion that prognosis cannot be based on any single sign such as the depth of the coma the intensity of anaemia or the urea content of the blood but that a combination of signs may afford a guide. The duration of coma before the institution of treatment is of great significance. The combination of high blood urea, coma, and high parasite density is a grave omen. If the complement content of the blood falls to and remains at zero an early fatal result may be expected.

Recovery from a pernicious attack may leave the patient very susceptible to serious secondary infections to prevent which the authors recommend treatment with very large doses of penicillin

PETA, T Sul significato e l'origine delle emorragie petecchiali nei soggetti malarici [Significance and Cause of Petechial Haemorrhages in Malaric Patients] *Riv di Malarologia* 1948, Aug, v 27, No 4, 171-8 [19 refs] English summary (5 lines)

The author describes eight patients, all from Matemma or Gallabat, Asmara who were suffering from malaria and who had petechiae on the trunk or limbs or both. Though malaria may cause haemorrhagic lesions in severe infection good evidence is produced that the petechiae in the cases in question were due to a deficiency of vitamin C in the inadequate diet.

HENRY, A F X De la sérologie palustre à la thérapeutique du paludisme chronique [Serology in the Treatment of Chronic Malaria] *Bull Acad Nat Méd* 1949 v 133, Nos 9/10, 193-6

— Les bases biologiques du traitement des formes prolongées de l'infection palustre [Biological Bases of the Treatment of Prolonged Forms of Malaria Infection] *Ibid*, 196-8

— Quelques directives pour le traitement du paludisme subaigu et du paludisme chronique [Suggestions regarding the Treatment of Subacute and Chronic Malaria] *Ibid* 198-201

The author enlarges on the value of the melano-flocculation reaction which bears his name, during the treatment, as well as in the diagnosis, of malarial infections.

Chronic malaria is a general, focal and organic disease characterized above all by a deficient oxygen supply to tissues with all the damage that such a state of affairs may produce. Internal secretory glands and reticulo-endothelial tissues are specially involved. Treatment should have one of two ends in view. If the patient can leave his malarious environment the aim should be the total eradication of the infection, not always easy to obtain. In other circumstances the aim should be the restoration of a state of premunition in which the patient tolerates his infection with impunity.

The author's methods for the catalytic premunotherapy of subacute and chronic malarial infections have been previously described (see this Bulletin, 1948, v 45, 756).

HERRING E. R., PATT H. M. & LEAVITT H. J. Tolerability Studies of some New Antimalarial Drugs. *J. National Malaria Soc.* 1948 Dec., v 7 No. 4 322-9 3 figs.

This experiment was designed to test the tolerability or acceptability of four of the newer antimalarial drugs of suppressive value as compared with quinaquine [mepacrine] and a placebo (lactose). Nine hundred and fifty-five volunteer marine recruits were the subject of experiment. The value of the drugs as suppressants was not an object of the study. The drugs tested were given once a week, these drugs, and their weekly doses, were: SN-6911 0.6 gm. SN-7819 [Chloroquine] 0.3 gm. SN-8137 Oxychloroquine 0.6 gm. SN-11437 [metanilamido-5-chloropyrimidine] 0.0 gm. quinaquine 0.24 gm. The drugs and the placebo were all given in green tinted capsules after a mid-day meal. None knew which of the six preparations he was given.

After each drug administration the men were interviewed concerning the results of the previous dose and asked if they had any complaints. All complaints were recorded.

Criteria of tolerability were (a) refusal to accept the drug after it had been taken at least once (b) complaints attributable to the drug (number of individuals complaining) (c) sick bay admissions during the course of the experiment (d) rifle firing scores achieved during the experiment. The observations lasted six weeks.

Quinaquine was productive of most complaints and refusals to continue. SN-6911 was also significantly inferior to the other three drugs. SN-7819 (chloroquine) was the best tolerated causing almost as few complaints as did the placebo (34 complaints of various symptoms were attributed to lactose). Motor co-ordination as reflected by shooting scores was unaffected by the drugs.

WIJCKEL C. W. F. The Efficacy of Quinaquine and Quinine in the Treatment of *Plasmodium malariae* Infections. *Documenta Neerlandica et Indonesica de Morbis Tropici.* Amsterdam, 1949 Mar v 1 No. 1 83-6 4 graphs.

The author describes his experience in the treatment of *P. malariae* infections with quinine and quinaquine [mepacrine]. His patients were neurosyphilitics who had been infected, for the most part, by intravenous subinoculation. He compares his results with those obtained by VAN DER EYDEN (this Bulletin, 1948 v 45 699) who administered quinine in much larger doses and for a much longer period than does the author. He concludes that in cases of quartan malaria the results of treatment with 1 gm. of quinine a day are certainly as good as those with 2 gm. a day. The use of larger doses should be banished. Symptoms of toxication of any events are thereby averted. Quinine when given in proper doses kills many parasites but not all. A certain

amount of antigen comes into contact with the body cells. This stimulates to enhanced phagocytosis and to the secretion of antibodies. When these are present in sufficient numbers, the surviving parasites are killed off. Quinine should therefore be given in such dosage that the cells are not damaged."

CLARKE G H V. A Case of Mepacrine Dermatitis [Memoranda] *Brit Med J* 1949, July 9, 58

HILL, E & AMATUZIO, D S. Southwest Pacific Vivax Malaria. Clinical Features and Observations concerning Duration of Clinical Activity. *Amer J Trop Med* 1949, Mar, v 29, No 2, 203-14, 3 figs [40 refs]

Between July 1, 1945 and April 1, 1948, 328 patients with *P vivax* infections that had been acquired in the south-west Pacific were studied in the Veterans' Hospital, Minneapolis. All had received suppressive mepacrine medication while in the Pacific, this had usually been discontinued on their return to the United States. Since discharge from the Service all had resided in a non-malarious region of the United States.

Chills, fever and malaise ushered in the attack in almost all cases. Other prodromal symptoms were present in 46 per cent. Enlarged spleen was noted in 37.6 per cent of patients. Anaemia was not a marked symptom, the patients were well nourished. The haemoglobin level was not related to the number of attacks.

One hundred and sixty-nine patients were treated with mepacrine, 62 with chloroquine. Mepacrine dosage was 0.2 gm every six hours for five doses, then 0.1 gm thrice daily for six days. Chloroquine diphosphate dosage was 1.0 gm followed by 0.5 gm six hours later, then 0.5 gm on each of the second and third days. The relapse rates of comparable groups of patients treated with mepacrine and chloroquine were 60 and 56 per cent, respectively. The relapses after chloroquine treatment occurred much earlier. Chloroquine was in no way more effective than mepacrine. There were no symptoms of toxicity with either drug.

A study of the duration of infection was made in 155 patients, none of whom was treated with drugs likely to eradicate the infection such as quinine-plasmoquine or pentaquine-quinine. Infections were terminated in the first year in 24.5 per cent, in the second year in 52.9 per cent, in the third year in 18.3 per cent. Attacks were still occurring in the fourth year in 4.3 per cent. All the patients probably harboured multiple strains of Pacific *P vivax*.

CULWELL, W B, COOPER, W C, WHITE, W C, LINTS, H A & COATNEY, G R. Studies in Human Malaria. XX. The Intramuscular Administration of Chloroquine. *J National Malaria Soc* 1948, Dec, v 7, No 4, 311-15 [10 refs]

Chloroquine was given intramuscularly to 16 young male volunteers who had been infected with the Chesson strain of *P vivax* by mosquito bite. It was given as the hydrochloride in sterile unbuffered aqueous solution containing 45 mgm of the salt (40 mgm base) per ml. The pH of the solution was 5.6. Treatment of each attack was begun on the third day of patent parasitaemia if the oral temperature had reached 102°F by 8 a.m. on that day. Three systems of dosage were used: single injection of 200 mgm (base), two injections of 200 mgm each, four-hour interval, single injection of 300 mgm. Injections were made in the gluteal muscles.

The highest plasma concentrations of chloroquine were obtained 15 minutes after injection, in all but four cases. The highest concentration observed in any subject was 490 mgm. per litre. Clinical response was rapid in all cases. There were no toxic reactions.

Where oral administration of chloroquine is not possible treatment can safely be begun by the intramuscular injection of 200 mgm. of base repeated after four hours if necessary. Treatment by mouth, to complete a course of 1.5 gm. of base in three days should be started as soon as practicable. *Norman White*

GIOVAXARDI, A. SEFCLORI, P. & DE NEGRI U. Il "Palusil" (N^1 -p-cloro(enil- N^3 -isopropil-bisguanide) nella terapia della malaria.—Nota II. Effetti del trattamento della malaria naturale da *Plasmodium vivax* (Paludrine (Proguanil) in the Treatment of Malaria. Note II. The Effects of Treatment of Naturally Acquired *P. vivax* Infections.) *Riv. di Malariologia*. 1949, Oct. v 27 No. 4 191-200 1 graph. English summary (7 lines).

This is a progress report of an investigation the authors were making on the value of palusil, Italian paludrine [Proguanil] in the treatment of malaria. Three hundred and twenty three patients suffering from *P. vivax* malaria were treated 201 from the Province of Venezia and 122 from the Province of Roma. The results were satisfactory. Various doses were prescribed. The best results were obtained with 0.3 gm. a day for 15 days followed by the same dose once a week for five weeks. Among 30 patients so treated only one relapsed on the 20th day after the end of treatment. The reduction in the size of enlarged spleens began after the first day of treatment. In more than 70 per cent of the patients treated with palusil the spleens were normal in size after the end of treatment. The drug was generally given after food and was well tolerated.

Blood counts in ten patients with chronic infections showed a marked increase in the number of red cells that resulted from treatment together with a return to normal of the differential leucocyte count. *Norman White*

WHITE W. C., COOPER, W. C., COATNEY G. R., CULWELL, W. H., LINTS H. A. & YOUNG, M. D. Studies in Human Malaria. XXI. The Cure of St. Elizabeth Strain *Vivax* Malaria by Pentamidine-Quinine administered during Acute Attacks or during Latency. *J. National Malaria Soc.* 1949, Dec. v 7 No. 4 316-331 fig. 10 refs.

Fifteen young white male volunteers were infected with the St. Elizabeth strain of *V. vivax* by mosquito bite. This strain produces an infection with a latent period of from 6 to 9 months between the early primary attack and the first relapse. All 15 men developed early primary attacks which became patent 11 to 14 days after the mosquito bites. The men were divided into three groups of five each. On the third to fifth day of patency the men of Group A were treated with concurrent pentamidine and quinine. The men of Groups B and C were treated with quinine alone. The doses (base) were: pentamidine 15 mgm. every 6 hours for 14 days; quinine 0.5 gm. every 6 hours for 14 days. The acute attacks were alleviated promptly in all cases.

Four months (120 days) after infection the following treatment was given: Group A none; Group B concurrent pentamidine and quinine; Group C quinine alone.

The men of Groups A and B had no late attack of malaria through 18 months of observation. All the five men of Group C developed late relapses 184 to 280 days after the original infection. These late relapses were terminated with pentamidine and quinine and no subsequent attacks developed during the following 18 months.

During the 15 courses of combined pentaquine-quinine therapy the complaints were abdominal cramps, 14, epigastric tenderness, 9, nausea, 6, anorexia, 4, nausea and vomiting, 3, tinnitus and dizziness, 5, urticaria, 2, fine macular rash, 1, fine papular rash, 1, tremor, 1, blurring of vision, 1. Only one man had no complaints.

During the 15 courses of quinine alone the complaints were abdominal discomfort, 2, epigastric tenderness, 1, nausea, 3, tinnitus, 3, dizziness, 5, urticaria, 1, fine macular rash, 1, diarrhoea, 1.

Concurrent pentaquine and quinine have clear-cut curative properties in the treatment of infections with the St Elizabeth strain of *P vivax*.

KLOPPER, S The Suppressive Action of Paludrine in Benign Tertian (Vivax) Malaria *Documenta Neerlandica et Indonesica de Morbis Tropicis* Amsterdam 1949, Mar, v 1, No 1, 50-54, 4 figs

These carefully controlled observations were made in Wormerveer, a town of 10,500 inhabitants in the Province of North Holland. Paludrine [proguanil] once a week was given to 607 adults and to 566 elementary school children from the middle of April to the middle of July, when malaria is most prevalent. Adults received 100 mgm., children 50 mgm., a week. A second group of 510 adults and 474 children received no paludrine but were as carefully observed as the first group. During the period of drug administration the incidence of malaria in the paludrine group was markedly lower than among the control group, the curve falling to zero at the end of May. After the cessation of paludrine the malaria incidence of the treated group rose rapidly, the total malaria morbidity of that group for the season being about equal to that of the general untreated population of Wormerveer. Paludrine delays the clinical attack.

Sixty-four patients who had suffered from one or more malaria relapses in 1946 were each given a tablet a week, 32 received 100 mgm paludrine the remainder sodium bicarbonate. Those who took paludrine regularly had no further relapse during the period of observation. 12 of the 32 patients receiving sodium bicarbonate suffered clinical relapses during this period.

HOFFMAN J & VAN RIEL, J. Bilan d'un an de lutte antimalarienne par pyréthrace des habitations. [Appraisal of the Results of a Year's Antimalarial Work by Treatment of Dwellings with Pyrethrum.] *Ann. Soc. Belg. de Méd. Trop.* 1948, Dec. 31 v. 28 No. 4 387-94

In Lenda, a mining settlement of the *Gauts Lacs Africains* Mining Company of the Belgian Congo, an experiment to control malaria by dusting dwellings with pyrethrum powder was begun in the middle of May 1947. The settlement was highly malarious. Imported labour recruited in non malarious localities suffered very severely. *A. gambiae* and *A. funestus* were very abundant. It was often possible to capture 5 000 or more adults of these species in a single dwelling. The houses were dusted with fresh and finely ground pyrethrum flowers. Dustings were done twice weekly, 40 gm. of powder being used on each occasion for each house. After some months when anophelines could no longer be found the amount of powder used was reduced by half.

The results were spectacular. The infant mortality rate was 10 per 1 000 live births during the first half of 1947. It fell to 8.6 in the second half of that year and to 5.2 in the first half of 1948. No such fall was evident in control untreated areas. The mortality rate of older children was 4.3 per thousand during the 12 months preceding the experiment. It fell to 0.9 during the first 12 months of the pyrethrum treatment.

Previous to the experiment malaria parasites could be found in the blood of infants within a few weeks of birth. After a year of treatment of the camps malaria parasites were found in only one of the 420 infants under one year of age examined.

The rare cases of malaria that are now seen are either relapses or infections contracted elsewhere.

Norma HALL

ETNERINGTON D. DDT as a Residual Insecticide against *Anopheles maculipennis*. [Correspondence.] *Nature* 1949 July 2, 32.

The author refers to Meirhead THOMSON's findings in Africa this Bulletin 1949 v. 46 439 that DDT had an irritant effect on *A. phaeocephalus* in houses. The present author had the impression in Italy in 1944-45 that *A. maculipennis* var. *labialis* reacted similarly when DDT spraying (5 per cent in kerosene) was used against "domestic" resting places. It seemed to have repellent rather than a lethal effect.

He had recorded this experience and its possible implications with proposals for its investigation in an official report but Service conditions precluded the matter being followed up and the necessary experiment which he suggested could not be completed. He points out that Meirhead THOMSON's independent findings with *A. gambiae* support his own earlier observations and he now adds that he considers that the value of DDT as a malaria control measure is also open to doubt in areas where *A. maculipennis* var. *labialis* is the vector. [No experience with *G. morsitans* is recorded.]

DE VEGT, L. Larvicida a base di polvere di sughero di DDT. Cork Powder and DDT as a Larvicide. *Riv. di Malariologia* 1948 Oct. 27 No. 5 213-20. [En. lish summary (8 lines)]

Cork powder, by product of the cork industry, consists of amorphous granules from 1 to 47 μ in diameter when applied to the surface of water in quantity not less than 150 gm. per square metre kills anopheline larvae therein by asphyxia. The large quantity required precludes its use as a practical larvicide.

If the cork powder be immersed in kerosene containing 5 per cent DDT—1 kilogramme of powder in a litre of kerosene—the resultant product has a potent larvicidal action against both *Anopheles* and *Culex* when sprayed on water in quantity not less than 25 gm per square metre. In none of the experiments did this larvicide cause any damage to fish, including *Gambusia*. The low cost of cork as a waste product makes this a cheap way of destroying larvae.

HAAS, V. H., WILCOX, Aimee & COLEMAN, Nell. Modification of *Plasmodium gallinaceum* Infections by certain Tissue Extracts. *J. National Malaria Soc.* 1949, Mar., v. 8, No. 1, 85-99 [17 refs.]

The fact that various laboratory mammals were refractory to *P. gallinaceum* infection suggested to the authors that some substance or substances inimical to the parasite might be present in their tissues. Extracts of various mammalian tissues were therefore prepared and their effect on *P. gallinaceum* was tested *in vitro* and *in vivo*. Since extracts prepared from chickens in a similar way also showed some inactivating effect it appears that a number of other factors are associated with resistance to infection. In the *in vitro* test, with suitable controls, it was found that exposure to saline extracts of pooled mouse tissues inactivated to some extent blood and exoerythrocytic forms of the parasite, also sporozoites as judged by the resulting infection rate in chick embryos inoculated by various routes. Extracts of spleen of various mammals and of chickens affected sporozoites, exoerythrocytic and especially erythrocytic forms of *P. gallinaceum* so that the infection rate in chickens inoculated with these parasites was greatly reduced. Bovine spleen extracts were, however, toxic to chickens, causing necrosis and gangrene at the site of subcutaneous inoculation [the actual site of inoculation of the parasites and extracts is not stated, but if inoculation of both was made at the same spot the necrotic action on tissues mentioned would doubtless affect the injected parasites]. An extract from chicken and bovine blood showed similar properties and toxicity but in lesser degree than those from spleen. It is possible that red or white blood cells present in the spleen were the source of activity. An unsuccessful attempt was made to characterize the active substance, it appeared, however, to be protein.

TERZIAN, L. A., STAHLER, N. & WEATHERSBY, A. B. The Action of Antimalarial Drugs in Mosquitoes infected with *Plasmodium gallinaceum*. *J. Infect. Dis.* 1949, Jan.-Feb., v. 84, No. 1, 47-55, 1 fig.

The present investigation is a continuation of earlier studies by the senior author and Weathersby [this *Bulletin*, 1948, v. 45, 767, 1949, v. 46, 609] who indicated that a correlation existed between the activity of prophylactic drugs in *P. gallinaceum* infections of chickens and in infected mosquitoes. Those substances which protected the chicken host against sporozoite infections also arrested oocyst development in the mosquito, whereas suppressive drugs exerted no such effect. A prophylactic drug in the invertebrate host is defined as one which is effective against presporozoite stages and prevents formation of the latter.

About 100 to 150 *Aedes aegypti* or *Anopheles quadrimaculatus* were fed on each different concentration of drug prepared in 4 per cent. sugar solution. Mortality was correlated with the level of drug concentration. Feeding on the drug solutions was begun 48 hours before an infective blood meal and continued during the course of infection. Development of oöcysts was followed by dissection of the hosts and intensity was gauged by their number and that of sporozoites present. Infectivity of sporozoites was tested by inoculation to chickens.

A number of drugs which act as suppressive agents in the vertebrate host including quinine, atabrin (mepacrine), plasmoquine (pamaquin) and others had no effect on oöcyst development or sporozoite production in the mosquito whereas sulphadiazine, metachloridine (SN 11 437, 6-metanilamido-5-chloropyrimidine) and paludrine which are prophylactic in the chicken prevented oöcyst development and sporozoites were therefore absent. This was found by calculation to be more than a chance relationship and the results confirm the earlier findings of the author. Similar relationships held in the case of *P. falciparum* and its vector *A. quadrimaculatus*. In this case paludrine was the only active drug. The application of these methods to the search for drugs prophylactic in human malaria is obvious and has the advantage that if levels of drug are adequate effects can readily be judged by mosquito dissection followed by microscopical examination. Photomicrographs of mosquito stomachs taken seven days after an infective blood meal illustrate this fact. It was noted that the effect of prophylactic drugs was exerted late in oöcyst development and the drugs could therefore be withheld for some days after an infective meal and still show activity. A particular phase in the oöcyst developmental cycle appears to be specially vulnerable to drug action. The infectivity of developed sporozoites was not affected except by plasmoquine. The action of metachloridine and sulphadiazine but not of paludrine was antagonized by para-aminobenzoic acid and this suggests that the two former substances interfered with the para-aminobenzoic acid metabolism of the parasite as does sulphadiazine in the case of bacteria. J. D. Fildes

KNOPPERS, A. T. Twofold Quinine Resistance of *Plasmodium gallinaceum* Induced by Regular Administration of the Drug. *Documenta Neerlandica et Indonesica de Morbis Tropicalibus*. Amsterdam, 1949 Mar 1, No. 1, 55-63, 40 refs.

The production of strains of avian, monkey and human plasmodia (*P. vivax*) resistant to various antimalarial drugs has been reported in this *Bulletin* from 1942 onwards. The present author described previously a strain of *P. gallinaceum* with two-fold resistance to quinine (this *Bulletin*, 1949, 45 [56]) of which further details are now given. The method employed was to treat seven-day-old chicks orally with 10 mgm. per kilo. of the drug and to transmit the treated strain by blood inoculation into fresh hosts. At the end of 16 weeks treatment the dose of quinine was doubled and after 28 weeks a two-fold resistance was established and could not be increased. The resistance persisted when quinine was withheld for about 25 weeks but was slightly diminished after the first mosquito passage though not on subsequent passages. Resistance was also shown to mefloquine and to a lesser degree to mefloquine or quinoline. There was no resistance to atabrin, mepacrine, paludrine (pregnam), chloroquine or sulphamerazine. On the other hand the strain was more than usually sensitive to pamaquin, plasmoquine, pentamidine and isopentaquine. On passage by means of erythrocytic film resistance was retained. There is at present theoretical discussion on the significance of these results. J. D. Fildes

SICCA, G T L'azione del Farma 01015 (Paludrina) sulla infezione da *P. gallinaceum* [The Action of Paludrine [Proguanil] in *P. gallinaceum* Infections] *Riv di Malarologia* 1948, Oct, v 27, No 5, 201-12 [13 refs] English summary (3 lines)

This is a record of experiments to determine the efficacy of an Italian preparation of paludrine hydrochloride [proguanil] in the treatment of *P. gallinaceum* infections. Chickens were used. In one group of birds, infection was produced by the injection of 0.2-0.25 cc of citrated blood, taken from a bird in the acute stage of the infection, into the pectoral muscle. In a smaller group 0.4 cc of an emulsion of brain tissue of an infected bird in normal saline was injected intramuscularly. All the untreated control birds of less than 120 gm weight inoculated with infected blood died during the acute phase of the attack, no exoerythrocytic forms were found at autopsy. Some of the heavier birds, from 300 to 550 gm weight, survived the acute phase to die later during a recrudescence, with exoerythrocytic forms in the internal organs. Most of the birds infected with brain emulsion containing exoerythrocytic forms died during the acute attack with erythrocytic forms in the blood, the acute phase began from 7 to 12 days after inoculation.

Paludrine was given by mouth at different stages of the acute attack. A dose as small as 2 mgm a day for 3 days had a definite influence in 4 chicks, the high parasitaemia was much reduced, and death was delayed to the 19th to 23rd day after inoculation. Four birds varying in weight from 110 to 400 gm who were given 5 mgm a day for 6 days recovered from the infection. One of these was killed on the 63rd day after inoculation, a very few parasitized red cells were found but there were no exoerythrocytic forms.

To test the prophylactic value of the drug, 7 birds inoculated with infected blood received 2 to 5 mgm paludrine a day for 6 days, beginning 4 hours after the inoculation. These birds were killed at different periods, when the corresponding control birds were suffering from an acute attack or, in two cases, on the 48th and 63rd days after inoculation. In only one living bird were parasites found in the peripheral blood, they were few in number and found on only three consecutive days, 30 days after inoculation. In 2 birds killed on the 16th and 48th day after inoculation a very few infected red cells were found. No exoerythrocytic forms were found in these birds. The experiments confirm the remarkable therapeutic and prophylactic activity of paludrine against *P. gallinaceum*.

Norman White

CANTRELL, W, KELSEY, F E & GEILING, E M K Sulfonamide Blood Levels in Prophylactic Tests against *Plasmodium gallinaceum* *J Infect Dis* 1949, Jan-Feb, v 84, No 1, 32-40

Certain sulphonamides have been found active in human, monkey and avian malaria. Although the hope was not realized, it appeared probable that a member of the group would be found to act as a prophylactic in human malaria. The experiments described here were undertaken to gain information on the blood levels of drug required to protect chickens from intravenous infection with sporozoites of *P. gallinaceum*. The drugs were given in the diet to chickens kept on a three-hour dark and light schedule. At the end of a light and dark period blood samples of 0.02 ml were collected daily or every second day for the determination of sulphonamides, generally in pooled samples, by BRATTON and MARSHALL's method (*J Biol Chem*, 1939, v 128, 537). Smears were examined for the presence of parasites and inoculation of blood to fresh hosts was used to detect the presence of latent infection in treated birds. In all, 13 experiments were performed in which groups of 5 chickens were given various

drug diets and 5 to 10 chickens served as controls in each case. Protection was afforded by sulphapyrazine, sulphadiazine, sulphamethazine and sulphamerazine in that order, 50 per cent of the chickens being protected by blood concentrations respectively of 2.6, 3.1, 4.7 and 7.0 mgm. per 100 ml. There was a correlation between the protection afforded and the persistence of drug in the blood. Besides those mentioned 61 other sulphonamides were tested for prophylactic activity of which 19 were effective in the doses used, most however being inferior to sulphadiazine in this respect. The disadvantages of the drug diet were that the amount of drug ingested could not be accurately assessed and wide variations occurred in the blood-levels of chickens receiving the same diet. Differences in the rate of disappearance of drugs from blood were also noted. The protective power of the sulphonamides depended on other factors besides blood concentration. Some which failed to protect caused considerable delay in the appearance of the parasites. The relation of structure to activity and drug concentration in the blood is discussed. J. D. FALKER

GREENBERG, J. Hypersensitivity to Sulphadiazine of a Chloroquine-Resistant Strain of *Plasmodium gallinaceum*. J. National Malaria Soc. 1949 Mar. v. 8 No. 1 80-84 1 fig.

The author and his colleagues (this Bulletin 1949 v. 46, 119) produced evidence to show that there was a synergism between chloroquine (proguanil) and sulphadiazine when used to treat *P. gallinaceum* infections of chickens. He has now investigated the possibility that a chloroquine-resistant strain of this organism might show increased sensitivity to sulphadiazine. Such a strain was therefore prepared by treatment of chicks with 0.03 mgm. of chloroquine hydrochloride per gm. of body weight once or twice during each passage and resistance was 16 to 2 fold from the 18th to 41st passage. During earlier passages and up to the 41st the resistant strain was at its maximum 8 times more sensitive to sulphadiazine than the normal. In later passages when chloroquine treatment was discontinued hypersensitivity to sulphadiazine persisted. As shown by others, the resistant strain was normally sensitive to quinine, chloroquine and pamaquin (plasmoquine). The author suggests that his findings indicate an attack by the two drugs in question on different enzyme systems in the parasite. They are however at variance with the findings of HINSHOP and MCCONNACHIE (this Bulletin 1949 v. 48, 119) who produced resistance to sulphadiazine in *P. gallinaceum* after 1 month treatment which was unaffected by mosquito passage and involved the simultaneous production of resistance to paludrine, proguanil. A paludrine-resistant strain after months of contact with the drug was also resistant to sulphadiazine. These conflicting results of the different authors require further investigation. J. D. FALKER

McGURR, R. B. Infection of Mammalian Erythrocytes by the Avian Malaria Parasite, *Plasmodium lophurae*. Proc. Soc. Exper. Biol. & Med. 1949 May v. 1 No. 1 87-91 1 fig.

Heavy infections of *Plasmodium lophurae* can be obtained in chicken embryos also and the author refers to investigation in progress under publication. Mammalian erythrocytes will survive for varying periods if introduced intravenously into the chicken embryo. Dog, rabbit and guinea-pig cells do not adapt themselves well to transfer but human and murine erythrocytes retain their morphology for considerable periods. Accordingly the author infected 10-day chick embryos with *P. lophurae* (24th passage strain in embryos) and ten days later inoculated them intravenously with 0.1 cc. of twice washed erythrocytes. The parasites only

rarely invaded human corpuscles but mice cells were readily parasitized (up to 0.1 per cent). The embryos usually showed a proportion of 1/2 mammalian to avian erythrocytes. The foreign cells were invaded after 12 hours, pre-segmenting forms were seen after 32 hours and mature schizonts in 36 hours. Band forms occurred, the pigment was in small golden-brown spheres and 5-11 merozoites in a rosette were produced. The mouse cells became enlarged but not stippled. No gametocytes were found.

In vitro, whole mouse blood plus infected chick embryo blood cultured by Trager's method [this *Bulletin*, 1947, v 44, 1046] showed a similar invasion of the mouse erythrocytes by the parasite.

[This paper appears to the reviewer to be of considerable importance and the results indicate that the method will help in the solution of a number of problems in immunity, in the obscure subject of gametocyte production and in the general relationships of the different species of *Plasmodium*. Many queries suggest themselves: could the infection continue if the blood were returned to mice, would continued passage under these conditions increase the susceptibility of the mouse corpuscles to infection and, finally, how would other parasites react to such changes in environment?] P C C Garnham

BLACKWATER FEVER

RAOULT, A., AUFFRET, C., TANGUY, F. & MARTIN, M. L'acide ascorbique dans le traitement de la fièvre bilieuse hémoglobinoïdique [Ascorbic Acid in the Treatment of Blackwater Fever] *Bull Méd de l'Afrique Occidentale Française* 1948, v 5, No 1, 161-6.

Extremely low blood ascorbic acid levels were found in cases of acute and chronic malaria. In the blood of six out of nine patients who developed blackwater fever only immeasurable traces could be detected. Accordingly, persons suffering from this disease thereafter were given large doses of vitamin C, 200 mgm intravenously every four hours, in addition to their other treatment with good clinical results.

It is known that fever causes increased utilization of ascorbic acid and lowered blood and tissue levels, and, further, that ascorbic acid is a factor in maintaining corpuscular integrity by inhibiting liberation of histamine and by its antagonistic action to hyaluronidase. The authors consider that a critical lowering of ascorbic acid levels may be a major factor in precipitating the onset of blackwater fever and that this catastrophe might be prevented by administering large doses of vitamin C to all patients with malaria.

TRYPANOSOMIASIS

CONGO BELGE FONDs REINE ELISABETH POUR L'ASSISTANCE MEDICALE AUX INDIGÈNES DU CONGO BELGE RAPPORT SUR L'ACTIVITÉ DURANT LES ANNÉES 1946 ET 1947 [DE BRAUWERE, P.] *Maladie du Sommeil* [Sleeping Sickness] pp 50-67, 1 diagram & 2 maps

For the preceding Forearm Report, covering the years 1939 to 1945, see this *Bulletin*, 1948, v 45, 816. The present Report as a whole is reviewed separately [*ibid* 1949, v 46, 785]. In 1946 and 1947 the measures against sleeping sickness continued to consist mainly of mass treatment and

chemoprophylaxis with only slight attention to entomological control. The situation continues to improve as shown by a further decrease in the Index of New Cases. In the Kwango Sector now the main scene of operations, the index was 0.47 per cent (2,862 new cases) in 1948 and it had fallen to 0.18 per cent (974 new cases) by 1947. Chief credit for the improvement is accorded to the procedure of mass prophylaxis, which is being increasingly carried out with pentamidine or propamidine replacing suramin for this purpose.

Arsenic-resistant infection has been a considerable problem, and the report refers to the discordance between the contention that arsenic-resistant strains are characterized by feeble infectivity and transmissibility (see Hoar this Bulletin 1947 v. 44 1049) and the field observation that when a strain becomes resistant it also seems to cause a flare-up of the endemo-epidemic situation. However the rising incidence of arsenic-resistant cases seems now to have been stemmed by the increasing use of mass prophylaxis.

In the 12 years up to December 31st 1947 the Fordians has treated, in the Kwango Sector 57,177 sleeping sickness cases of whom 87 per cent. were cured, 21 per cent. are still under treatment and 1 per cent. have disappeared, and only 5.4 per cent. have died. Detailed statistics are given for each sub-sector.

E. M. Lowe

WILCOCKS R. G. Determination of Proteins in Cerebro-Spinal Fluid. [Correspondence.] *Nature* 1949 Feb 29 329-30

In view of the need felt by many medical men concerned with sleeping sickness for improved methods of estimating the protein content of cerebrospinal fluid the author working in the Government Chemical Laboratory in Accra has elaborated a method depending on the xanthoproteic reaction. This obviates some of the objections inherent in existing methods which depend on the estimation of opalescence or volume of precipitate.

The detail cannot be usefully presented in the form of an abstract and the original, very concise paper should be consulted by those interested. (The method seems rather too complicated to be likely to find its way with field officers who have no spare time or facilities for refined chemical procedures.)

F. M. Lowe

GUIN M. Glycémie et glycogène dans la pleurésie d'état de la trypanosomiose humaine. Glucose Content of the Blood and Cerebrospinal Fluid in Sleeping Sickness. *Bull. Méd. de l'Afrique Occidentale Française* 1949 v. 5 N. 1 93-7

Glucose estimations were made on the blood and cerebrospinal fluid in 71 poorly nourished patients in both stages of sleeping sickness. Specimens were taken 12 hours after the last meal. Control observations were made on 49 uninfected subjects. No significant difference was found between the infected and the uninfected groups in respect either of the blood or of the cerebrospinal fluid.

TOWN R. W. WILLS E. D. & WOXALL A. Action of Suramin on Enzymes. *Nature* 1949 May 7 705-6 11 ref.

The carbohydrate and oxidative metabolism of trypanosomes occurs at relatively very high rate. One theory of the mode of chemotherapeutic action of suramin (antryptol Mayer 216) is that it combines with or otherwise inhibits enzymes in the trypanosome which are necessary for this vigorous metabolism. The authors are therefore studying the action of suramin on various enzymes.

systems, including those of the trypanosome. So far their attention has been confined mainly to the yeast enzymes concerned with carbohydrate metabolism and some other enzymes selected for special reasons.

It had previously been found that suramin is toxic to fumarase but not to urease [this *Bulletin*, 1932, v 29, 295]. The authors confirm that urease is not affected at pH 7.5, but they find that marked inhibition occurs at pH 5. This is perhaps related to the presence of a urea structure in suramin, and it may depend on competitive inhibition though it may alternatively be due to the compound's sulphonic acid groups. The inhibition is evidently of a specific nature, since it is not exercised against enzymes in general when tested at pH 5 as might have been expected in view of the fact that suramin combines with a variety of proteins at that hydrogen ion concentration.

Trypsin has also been found to be much more sensitive to suramin than was previously reported. This may be due to the similarity between the urea linkage of suramin and the peptide linkage of proteins.

The fermentation of glucose by yeast juice is inhibited by suramin in concentrations considerably below those that might be present in the blood after dosages such as are used in clinical practice.

SCHLEYER, W. L. & SCHNITZER, R. J. **The Inhibition of the Anti-Trypanosomal Activity of Arsenoso Compounds and Acridines by Esters and Amides of Organic Acids** *J Immunology* 1948, Oct, v 60, No 2, 265-76 [18 refs.]

This interesting paper describes a new category of interference effect against the anti-trypanosomal activity of arsenicals and acridines. Some of the categories of interference with arsenicals already well established are those due to the following —

- (i) Parafuchsin [BROWNING and GULBRANSEN, this *Bulletin*, 1922, v 19, 882]
- (ii) Thiol compounds [VOEGTLIN, DYER and LEONARD, this *Bulletin*, 1924, v 21, 414], development of which led to the discovery of BAL as an antidote for arsenical poisoning by the team led by PETERS during the recent war.
- (iii) *p*-aminobenzoic acid in relation to *p*-arsenosphenylbutyric acid [WILLIAMSON and LOURIE, this *Bulletin*, 1947, v 44, 48]
- (iv) Melamine, in relation to melaminyl arsenicals [WILLIAMSON and LOURIE, this *Bulletin*, 1948, v 45, 413]

The new interference phenomenon has been demonstrated both *in vitro* and *in vivo*. The two arsenicals mainly studied were both phenylarsenoxides, namely mapharsen and N-(*p*-arsenosobenzyl)-glycineamide hydrochloride, the acridine was acriflavine. The interference was exhibited by simple esters and amides of substituted benzoic acids (e.g. methyl-*p*-hydroxybenzoate and *p*-hydroxybenzamide), and by corresponding nicotinic acid derivatives. The acids themselves, tested as sodium salts, were inactive. When the newly discovered antagonists were used together with thiol substances, an additive or synergistic inhibitory effect was observed. A similar synergistic inhibition was noted, in respect of acridine but not of arsenical activity, when the new compounds were used in conjunction with yeast nucleic acid, which is known to be an inhibitor for the antibacterial effects of acridines.

Arsenic acids and arsenobenzenes were not antagonized by the new substances, nor were trivalent or pentavalent antimonials.

A table shows various points of difference between the features of inhibition exercised by some of the known types of interfering agent. For example, the new compounds do not affect toxicity of the arsenicals for the host, as do thiol compounds, again, inhibition by the new compounds is demonstrable both *in vitro* and *in vivo*, while inhibition by parafuchsin is said to be demonstrable only *in vivo*. The authors accordingly infer that essentially

different mechanisms of inhibitory effect are involved. They have shown that methyl *p*-hydroxybenzoate not only inhibits the antagonistic effect of aromatic compounds on isolated enzyme systems of *Bacter coli* but may even exert a stimulant effect on some of these enzymes. This suggests a possible basis for the mechanism of inhibitory effect of the substances concerned.

SCHOTAPPEL E. B. & GREENSPAN E. M. The Pharmacology Mode of Action and Therapeutic Potentialities of Stilbamidine Pentamidine Propamidine and other Aromatic Diamidines—a Review *Medicine* 1945, Sept., v 27 No. 3 37-77 [193 refs.]

This is a detailed and comprehensive survey of the development and present status of the diamidines as therapeutic agents. They are of course best known as remedies for protozoal infections, and their use in this connexion has been adequately reviewed in this *Bulletin* as the work has proceeded. Those who are not familiar with the progress of research on the diamidines in fields other than that of tropical medicine may be interested to know that there have been several surprising and significant developments in these other fields. Propamidine might have become very widely used as a wound disinfectant if not for the discovery of sulphonamides and penicillin. More striking is the fact that diamidines have some degree of tumour-inhibiting activity. There is evidence that they combine with and inactivate specific nucleic acids or nucleoproteins thus preventing the growth of certain tumour cells as studied in laboratory animals and in tissue cultures. This property apparently also underlies the fact that stilbamidine has a remarkably ameliorative though not a curative effect on multiple myelomatosis in man. Of more direct interest to tropical workers is the finding that propamidine exercises an inhibitory effect against a limited range of fungi *in vitro* *Bulletin of Hygiene* 1943 v 20 760. The treatment of fungus diseases by diamidines might accordingly be worth investigating.

[The authors state that the early work of LOURIE and LOWIE (this *Bulletin* 1940, v 37-404) established the aromatic diamidines as potentially active agents against infections with African trypanosomes such as *T. brucei* and *T. gambiense*. It might here be mentioned, though, that all the published work up to the present on field trials is distinct from trials in laboratory animals with the aromatic diamidines against the trypanosomes of man have been carried out against *T. gambiense* infections. It is a curious gap in the study of these compounds that no report has yet appeared on their action against naturally occurring *T. brucei* infections.]

FULTON J. D. & GOODWIN T. W. Hydrolytic Changes in Solutions of Stilbamidine *J. Pharm. & Pharmacol.* London 1947, 1 v 1 No. 1 11-16
Abstract on p. 13 of

Working in the Sudan, HENRY (this *Bulletin* 1944, 41 1186) found that among the changes undergone by stilbamidine solution in diffuse daylight there is hydrolysis of the amidine groups to the corresponding mono- and di-amides. In fact he isolated and identified 4-carbamyl-4-aminodiphenylamine from such solutions. HENRY J. *Chem. Soc.* (1945 870) 1 (England 1947) (this *Bulletin* 1948 v 45 508) found that the only product formed by exposure of stilbamidine solutions to light was 1,3,4-tri-4-aminodiphenyl) endobutane.

In 1947, Drs Henry and Kirk sent the authors some bottles of stilbamidine hydrochloride solution prepared in the Sudan and kept since 1941 and 1942 in the dark or in diffuse sunlight. The solutions contained two types of crystalline deposit, one of which the authors have confirmed as 4-carbamyl-4'-amidino-stilbene and the other they have identified as 4,4'-dicarbamyl-stilbene.

Since deposits had never been observed in stilbamidine solutions kept for more than a year at room temperature in England, the authors prepared further solutions which they then subjected to various conditions of light and temperature over a period of 6 months. Under certain conditions deposits appeared consisting of mono- and diamides identical with the products formed in the Sudan. Temperature is apparently important, for the monoamide (though only traces of diamide) were obtained by keeping solutions at 37°C for 6 to 17 weeks, while no amides were formed at laboratory temperatures. Occasional exposure to electric light also increased the yield considerably, as compared with solutions kept in complete darkness. Good yields of both amides were readily obtained by autoclaving for several hours at 1 to 2 atmospheres pressure.

Tests showed the monoamide to be more toxic than stilbamidine and inactive against *T. rhodesiense* and *T. congolense* infections in mice. Similar tests with the diamide were not possible because of its relative insolubility. Studies of fluorescence on ultra-violet illumination showed that stilbamidine is selectively concentrated at the blepharoplast and at a point near the anterior end of both *T. rhodesiense* and *T. congolense*, while the monoamide is diffusely distributed throughout the bodies of these trypanosomes.

Autoclaving solutions of stilbamidine for only 20 minutes at 5 lb pressure, the method used by OASTLER and FIDLER [this *Bulletin*, 1946, v 43, 1029] did not produce any demonstrable chemical change and did not increase the toxicity of the solutions for mice. It is therefore suggested that the lesions described by these workers in dogs treated with such solutions were due to unchanged stilbamidine.

NODENOT, L. Note sur une infection accidentelle avec une souche de *Trypanosoma gambiense* [An Accidental *T. gambiense* Infection] *Bull. Soc. Path. Exot.* 1949, v 42, Nos 1/2, 16-18.

The infection was accidentally contracted in the laboratory in Paris and is evidently the one mentioned by LAUNOY [this *Bulletin*, 1949, v 46, 337]. There was an incubation period of 10 days, followed by regular intermittent bi-quotidian fever, with severe headache and general symptoms. Parasites were numerous in the blood, and the spleen was enlarged. Lymph glands were not palpable and the cerebrospinal fluid was normal. Lomidine was given intramuscularly, 0.2 gm (i.e., 3.25 mgm per kgm) daily for 5 days. Trypanosomes disappeared the day after the first dose, and the original symptoms and signs rapidly cleared up. However, the patient began to complain of pain in the buttock, where a tender induration could be felt.

There was a rest-period of 8 days, and another 5-day course of lomidine treatment was then started. After the first injection the patient complained of a bitter taste in the mouth, a feeling of constriction in the throat, recrudescence of the pain in the buttock, difficulty in walking, and weakness. The symptoms became worse during treatment, which was accordingly stopped after the third injection. It took 6 weeks to recover from these symptoms, which the author ascribes to saturation of the body with the drug, and which were reminiscent of those described by SICÉ in another accidental laboratory infection treated with pentamidine [see this *Bulletin*, 1948, v 45, 876].

BRAUDINENT R. BROCHEY L. & PEZZIAT J. Not sur l'action curative du diméthino-diphénoxy-pentane administré par voie orale dans la trypanosomiase humaine africaine. [Treatment of Sleeping Sickness by Lomidine administered Orally.] *Bull Soc Path. E et.* 1949 v 4. Nos. 1/2. 18-22.

Twenty-one cases of *T. gambiense* sleeping sickness, early and late were treated orally by lomidine (dimethanesulphonat of pentamidine base). The drug was given either in a single dose or fractionated every day for 5 days. The daily dose for most patients was 20 to 30 mgm. per kgm. A total for the 5 days of 120 mgm. per kgm. was perfectly tolerated by some but others who received 73 and 114 mgm. per kgm. suff. red from diarrhoea and vomiting.

In 60 per cent. of cases the trypanosomes had disappeared from the blood and cerebrospinal fluid within 24 hours of a first dose of 20 to 30 mgm. per kgm. and in all cases early and late they had disappeared by the end of treatment courses varying from 114 to 150 mgm. per kgm. for the period of 5 days.

Of 9 first-stage patients there were 2 relapses within a fortnight. The other 7 have been under observation for periods of 1 to 5 months. No information is yet available on the fate of the second-stage cases.

The authors admit that the oral route appears to give therapeutic results inferior to those obtained by injection but they are undeterred from exploring the potentialities of oral administration for prophylaxis. Only an experiment conducted on a vast scale will permit the fixing of optimal prophylactic dosages. We propose to carry out such an experiment. E. M. Lewis

GASQ M. Action de la Lomidine (251^{er} R.P.) sur la glycémie des trypanosomés en 1^{er} et 2^{ème} périodes. (Premiers résultats.) Action of Lomidine on the Blood Sugar in Sleeping Sickness. *Bull. Méd. de l'Afrique Occidentale Française* 1949 v 5 No. 1. 99-103. 1 folding chart.

Blood sugar estimations were made on 8 patients undergoing treatment by lomidine (dimethanesulphonat of pentamidine base) for the early & late stage of sleeping sickness. Treatment was by 3 mgm. per kgm. nit a monocularly every alternate day for 5 injections. The blood was examined not less than 1 hour since the last meal specimens being taken immediately before an injection and then at intervals of 10 minutes for one hour.

Results were similar in the two stages of infection. There was an increase from an average of about 83 mgm. per 100 cc. to a peak 1108 mgm. in 20 minutes. There was then a drop to about 80 mgm. at 30 minutes, followed by a gradual rise to the original level at the end of the observation period of one hour. E. M. Lewis

FRIEDHEIM, E. A. II. VOGLZ, H. J. & BERNAN Rose L. Un composé organique stibé curatif et prophylactique dans la trypanosomiase expérimentale. An Organic Antimony Compound with Curative and Prophylactic Activity in Experimental Trypanosomiasis. *Bull. Méd. de l'Afrique Occidentale Française* 1949 v 5 No. 1. 85-8.

This is substantially a French translation of an earlier paper by FRIEDHEIM and BERNAN this *Bulletin* 1946, v 43. 11-4 with a few omissions and with additional data showing that the prophylactic action of the compound in question (M.b) is superior to that of uramin (morany) for *T. equiperdum* infections of mice. One-sixth of the maximum tolerated dose of M.b intraperitoneally protected all of five mice inoculated 68 days later but a comparable dose of uramin protected only 1 five mice tested on the 61st day. E. M. Lewis

LE ROUZIC, J & LAPEYSSONNIE, L Les médicaments nouveaux dans la trypanosomiase [The New Drugs for Sleeping Sickness.] *Bull Méd de l'Afrique Occidentale Française* 1948, v 5, No 1, 7-22

The author reviews French West African experience with FRIEDHEIM's melamnyl compounds, the diamidines, and EAGLE's "70A"

Melarsen —[See FRIEDHEIM, this *Bulletin*, 1941, v 38, 634, NODENOT, this *Bulletin*, 1949, v 46, 238] Of 22 late cases treated at Bobo with samples received since 1946, the cerebrospinal fluid was restored to normal in 8 and improved in 6 Unlike tryparsamide, which either renders the cerebrospinal fluid normal "immediately" or leaves it unchanged, melarsen brings it back to normal by slow stages over a period of some months There were no instances of damage to the optic nerve Melarsen is said to have the further advantage that it acts on trypanosomes both in the lymphatico-blood system and in the central nervous system, French workers hold that tryparsamide acts only in the latter situation

Melarsen oxide and *Mel B* (or *Melarsen B A L*) —[See FRIEDHEIM, this *Bulletin*, 1949, v 46, 711] These compounds are said to have the same advantages as melarsen, with the additional advantage that they can be given in a much shorter course of treatment The author appears to place greater faith in Mel B than in Melarsen oxide Success is claimed in 50 per cent of an unspecified number of second stage cases

MSb V —[See FRIEDHEIM and BERMAN, this *Bulletin*, 1946, v 43, 1124, and FRIEDHEIM, VOGEL and BERMAN, above] All the field observations on this compound till now have been made by Dr Friedheim himself For treatment, as distinct from prophylaxis, it has been given either alone or in combined courses with the following —

MSb III and *MSb B*, trivalent variants of *MSb V* —These three compounds are active against early cases, but they have an inconstant and superficial action on second stage cases

Diamidines —The aromatic diamidines have been curative in 90 per cent of early cases, but are undependable when there is even a slight alteration in the cerebrospinal fluid A directive was accordingly issued for all first stage cases in French West Africa and in Togo to be treated by pentamidine (5 injections of 3 mgm per kgm) which is regarded as rather more effective than propamidine Pentamidine will, however, gradually be replaced by "lomidine", the dimethanesulphonate of pentamidine base Among 1,011 first stage cases treated by pentamidine there have so far been 93.7 per cent cures, without any toxic complications There were only 2 cases (0.02 per cent) of chemo-resistance, and even these were not fully substantiated

70A or *p*-arsenosophenylbutyric acid —[See EAGLE, this *Bulletin*, 1946, v 43, 1017] Although this compound is ineffective in second stage cases when given alone, the results have been "brilliant", with 75 per cent successes, when it was given in combination with tryparsamide The compound is, therefore, said to be "not without interest" [CECCALDI *et al*, this *Bulletin*, 1948, v 45, 771 found combined treatment with 70A and tryparsamide to give results inferior to those obtained with established forms of treatment]

E M Lourie

WILSON, S G Drug-Resistance shown by Trypanosomes following "Antrycide" Treatment [Correspondence] *Nature* 1949, June 4, 873-4

At Entebbe the soluble salt of "Antrycide", in doses of 3-5 mgm per kilo, cured *T. simiae* infections in pigs One pig relapsed after 2 mgm per kilo of the relatively insoluble chloride, a second treatment with 5 mgm per kilo of the

soluble salt the sulphate [presumably methylsulphate] then failed to cure and the relapse strain was therefore considered to have become resistant.

Ten cattle were dosed with 2 gm. each of "Antrycide" sulphate and were then exposed to infection in a *G. pallidipes* area. Only one was still alive six months later and a strain of *T. congolense* passed from this animal into a calf treated with 5 mgm. per kilo of the sulphate. Two of six mice infected with this strain relapsed after treatment with 10 mgm. per kilo of the sulphate. A field strain collected in the same area from an untreated ox was cured by 0.5 mgm. per kilo.

Some animals re-infected several months after treatment with antrycide and re-treated with curative doses have developed cryptic but nevertheless fatal infections.

There is some evidence that *T. vivax* likewise quickly develops resistance to antrycide and there is evidence also that *T. congolense* which develops resistance to antrycide as a result of treatment with this compound becomes resistant at the same time to dimidium bromide.

Doses in excess of 10 mgm. per kilo [no doubt of the soluble salt] may be rapidly toxic: the animal dyes, 7 to 8 hours after treatment; in other cases gastro-enteritis develops 2 days after treatment and death occurs between the sixth and twelfth days.

E. M. Lounie

BARTISCH MED. J. 1949 June 11 1046-7 Control of Trypanosomiasis, Insecticides and Antrycide.

A general article based on an address by Dr D. G. Davey on the use of antrycide against trypanosomiasis in animals, particularly cattle in Africa. Although antrycide is a very promising drug and has been shown to give protection to cattle for at least 4-6 months, the possibility of naturally or artificially induced resistant strains of trypanosomes being encountered had to be born in mind. Only further trials and observations would show what contribution to the development of Africa could be expected from antrycide.

[See this Bulletin 1949 v. 46 338.]

LAUXOV L. & JEANPI. F. C. Nouvelle dix-mont de la prophylaxie chimique d'infection à *T. qu. perdom* d rat blanc par ingestion d diamidion-diphénocypentane. "New Observations on the Chemoprophylaxis of Trypanosome qu. perdom Infection in the White Rat by Ingestion of Diamidion-diphénocypentane." C. R. Soc. Biol. 1949 Mar. 143 Nos 5 & 6 328.

RUBIN, B. A. An In-vitro Assay for Trypanocidal Activity. J. Biol. & Med. 1948 Mar. 20 v. 4 81-83.

The classical method of YOFFE, ANAN and MISCHEVICH (this B. 1939 v. 27 237) for keeping pathogenic trypanosomes in culture for 24 hours depends on suspending these organisms in a concentration not above 1,000 per cmm in a medium composed of inactivated sheep or rabbit serum diluted with Ringer solution containing 0.2 per cent glucose. It is the method that the author takes his own technique which he describes in much detail, for the assay of compounds is as simple as is reported in the literature. The medium is composed of serum which is inactivated at 44°C for 1 hour and is diluted with twice its volume of Ringer solution. The medium is then centrifuged and the supernatant is used for all analyses. The final pH is 8.3 to 8.5. It is used at 1 mgm. per ml. then mixed with an equal volume of filtered Ringer solution with 0.5 mgm. per ml. of formalin so that there could be 40 to 150 trypanosomes and 10 to 20 times that

number of red blood cells, per cmm Drug solutions are added in amounts of 0.1 cc in distilled water to 0.4 cc of infected medium After 18 to 20 hours at 37°C the specimens are examined for trypanosomes and haemolysis

The Ringer glucose solution recommended by YORKE contained 0.9 per cent sodium chloride The author finds it better to use 0.75 per cent, and the final concentration of sodium chloride is even less after the solutions of drug in distilled water have been added

Some batches of medium completely failed to support trypanosomes, and thus the author attributes to the possibility that one of the donors from whom the pooled serum was obtained might recently have received an injection of an arsenical

E M Lourie

RUBIN, B A The Trypanocidal Effect of Antibiotic Lactones and of their Analogs *Yale J Biol & Med* 1948, Jan, v 20, No 3, 233-72 [38 refs]

The method described by the author [above], was used in order to investigate the trypanocidal potentialities of antibiotic lactones and their analogues Such substances are widely distributed in nature, particularly in lichens, moulds, and higher plants They occur in various natural dyes, in vitamin E, in the haemorrhagic principle of clover, in fish poisons, in insecticides, in numerous alkaloids, and in the digitalis glycosides Furan analogues of lactones occur in large amounts in corn-cobs, oat-hulls, and other plant substances, and one of these compounds, "Furacin" has already been shown to have some action on trypanosome infections [DODD, this *Bulletin*, 1948, v 45, 52] Pyrroles, nitrogen analogues of the furanes, are also widely distributed in nature, being best known in porphyrin pigments and in various animal and plant dyes

Altogether 44 compounds were tested "Furacin" was the most promising Delta lactones were more active than gamma lactone analogues, the three lactones with highest *in vivo* activity being 2-pentene-1,4-diol, penicillic, and coumalinic acids There was no correlation between *in vivo* and *in vitro* effects Thus clavacin was one of the most highly trypanocidal substances *in vitro*, but it was too toxic for any *in vivo* property to come into effect This substance has no surface tension reducing power at room temperature, and yet it is trypanocidal in a dilution of 1 in 1,000,000 at that temperature, a finding which the author says is at variance with theories which require some surface effect to occur before a drug can exercise its biological action In other instances there was high surface activity with neither trypanocidal nor haemolytic effect

Beside "Furacin" two other furanes showed some action *in vivo*, furfural and furfuryl alcohol Hydrogenated furanes were inactive

All nitrogen analogues tested were toxic and inactive *in vivo*

Most of the compounds were also tested against *Shigella dysenteriae* and *Staphylococcus aureus*, but no quantitative relationship was found between antibacterial and trypanocidal activities

VILAIN, P De la répartition géographique des glossines en A O F [The Geographical Distribution of Tsetse Flies in French West Africa] *Bull Méd de l'Afrique Occidentale Française* 1948, v 5, No 1, 107-16

Since the days of Roubaud and Bouet, some forty years ago, little that is new has been recorded about *Glossina* in French West Africa The author has carried out field work in the Upper Volta He has also received very many specimens collected by the medical staff in many districts Of a total of 120,000 specimens over 95 per cent were *G. palpalis*, *tachinoides* or *morsitans* Six other species were represented in small numbers

The paper reports geographical distribution, but in a rather general manner and without adding much precision to what is already known. We feel that in assessing the commonness of an insect the author relies too much on the number of specimens sent in. Some species may well be overlooked unless special methods of collecting are employed. P. A. B. v. m.

LOAND. PROTECT RATE. Annual Report of the Tsetse Control Department for the Year ended 31st December 1947 (SLAUGHTER, D. I. Acting Director of Tsetse Control) 18 pp 1948. Entebbe Govt. Printer [Shs. 1/30]

LE ROZIC. La prophylaxie agronomique. Un moyen de lutte pour l'assainissement des régions infestées. [Tsetse Control by Agricultural Methods.] Bull. Météo de l'Afrique Occidentale Française 1948, v 5 No. 1 117-22.

An autonomous sleeping sickness service was initiated in French West Africa in 1909. The present paper gives a general account of its work.

In most respects the methods in use are those which are generally familiar. We notice that the French put much emphasis on *prophylaxie agronomique* which is equivalent to the cultivation of the area which has been cleared, and its occupation by human beings. In making a waterside clearing close to an infected village they recommend a clearing 50 metres wide and 700 long, against *G. palpalis*; rather smaller clearings are said to be sufficient against *G. f. morsitans*. British experience would lead one to expect that such clearings are not sufficiently long to give complete protection from either of these insects. The French view is, we think, that this rather short clearing combined with diagnosis and treatment of human cases gives satisfactory results at least in savannah country. In forest where no doubt clearing would be very expensive both in primary cost and annual maintenance the author says that drugs alone do not overcome sleeping sickness: the number of new cases in successive years appears to demonstrate this.

The author attaches much importance to the sacred groves which often occur on the edge of a village. The local people cannot in any way interfere with these places, which form breeding places of *Glossina* in close contact with man. These places have been very numerous in the Upper Volta and their destruction is a most important measure in the reduction of fly and the control of sleeping sickness. We note that the French make much use of the labour of individuals in good health who are under treatment or have been recently treated for trypanosome infections. They can on occasion also obtain voluntary labour from villages.

The paper contains statistics for a number of years, showing the area cleared and planted, and the number of new cases of trypanosomiasis for different regions of French West Africa. P. A. B. v. m.

WHITESIDE, E. F. An Experiment in Control of Tsetse with DDT-treated Oxen. Bull. Entom. Res. 1949 May, v 40 Pt 1 123-34 ? figs. 17 refs.]

The object of this experiment was to determine the feasibility of exterminating tsetse flies by introducing a large number of cattle treated with DDT into their habitat. An area of thorn bush about 5 square miles in Tanganyika was chosen for the test. There was evidence that this territory was relatively isolated from external sources of tsetse flies owing to 1½ miles of clearing all round. The cattle were grazed in herds of 10 (Phase I) or 5 (Phase II) at the rate of 68 to the square mile. They were thus about 6 times as numerous as large game but less common than small game.

The DDT treatment was by a solution of 9 per cent DDT and 9 per cent resin in groundnut oil, applied all over the body (except the head) to give about 10 gm DDT per animal (450 mgm per sq ft). This treatment was applied weekly at first and later twice a week. Two months of this regular treatment did not harm the cattle.

The tsetse fly populations were assessed by 48 random catches per week (Two boys with a black cloth moving at random for two hours constitutes a "catch"). The results of the experiment were estimated by two arithmetical methods described in detail, one depends on changes in numbers on the test area, the other depends on relation to fly catches in an external control. A mean of the two estimates was considered most reliable.

According to the observed reductions, the mean kill of flies was about 70 per cent during Phase I and 95 per cent in Phase II. At the rate of progress observed, it was calculated that extermination of tsetse flies would take 22 months with herds of 10 cattle and about 9 months with herds of 5. Further splitting of the cattle would require too many herdsmen.

The slow progress of the reduction is due to tsetse flies feeding on animals other than the treated cattle. It would not be possible greatly to increase numbers of cattle because they were near the limit which can be supported on this type of country.

FAUST, E C. The Etiologic Agent of Chagas' Disease in the United States. *Bol Oficina Sanitaria Panamericana* 1949, May, v 28, No 5, 455-61 [24 refs]

This paper reviews the information available on the occurrence of triatomid bugs and mammals naturally infected with *Trypanosoma cruzi* in the United States of America. A list is also given of the bugs and mammals successfully infected experimentally. The data are conveniently set out in tables showing the names of the insects and the mammals, their geographical origin, and the references to the original papers from which the information has been extracted.

There is apparently no substantial published evidence that Chagas's disease occurs in man in the United States despite the considerable evidence of its occurrence as a disease of lower mammals. Seven mammals and seven species and two subspecies of triatomid bug have been found naturally infected.

It is concluded that the apparent absence of human infections in the presence of this animal reservoir cannot yet be adequately explained. Steps should, it is suggested, be taken meanwhile to control the bugs in infested premises and to carry on further investigations on the habits of the bugs.

PIFANO, F. Nouvelle trypanosomiase humaine de la région néotropicale produite par le *Trypanosoma rangeli*. Tejera, 1920. [A New Form of Human Trypanosomiasis of Neotropical Regions, produced by *Trypanosoma rangeli*. Tejera 1920.] *Bull Soc Path Exot* 1948, v 41, Nos 11/12, 671-80, 3 figs

This paper is, in large part, a recapitulation of work already published by Pifano and his colleagues on the occasion of the first successful direct cultivation of *Trypanosoma rangeli* from the peripheral blood [this *Bulletin*, 1948, v 45, 1072]. Previous findings of *T rangeli* in reduviid bugs or in human patients are discussed and the fact is noted that the authors have now

demonstrated that natural infections with *T. rangeli* are found in dogs as well as in man. In one dog the parasite was encountered in direct examination of the peripheral blood. Work on the parasite is in progress. A detailed description is given of the morphology of the parasite in the peripheral blood, in reduced bugs and in cultures. It is considered that *T. rangeli* is now established as a parasite of man and the dog and that in consequence there must be considered to be two forms of trypanosomiasis in the New World, due to *T. cruzi* and *T. rangeli*.

I. SARROUY C., AUBAUD-BATTANDIER R. & CANALIS R. Deux nouvelles observations de kala-azar infantile traitées par le "168 R.P." [Deux techniques d'administration du "168 R.P." Two more cases of infantile Kala Azar treated by 168 R.P. The Technique of Treatment.] *Péd. Méd.* 1947 Apr. No. 4 233-9. 1 fig. & 4 charts.

II. D'ESMOUGES J. R. & MESSERSCHMITT J. Kala-azar de l'adulte guéri par une seule cure de "168 R.P." [Kala Azar in an Adult cured by a Single Course of 168 R.P.] *Ibid.* 1948, Mar. No. 3 15-9. 4 figs.

III. MÉDECINE TROP. MARSEILLES 1948, July-Aug-Sept-Oct. No. 4 490-91. A propos du 168 R.P. et de son dosage dans les urines. [Concerning 168 R.P. and its Estimation in the Urine.]

I. For previous reports on the use of "168 R.P." against kala-azar see SARROUY *et al.*, (this *Bulletin* 1947 v. 44 55 and 207) and DIXON *et al.* *Ibid.* 1948.

The present report concerns two infants both very severely affected. The first patient was 13 months old, weighed 18.8 kgm. and had been ill for 5 months.

Anthelmintic given on alternate days for 3 doses was ineffective. But a 10-day course of 168 R.P. 90 mgm. per kgm. daily intramuscularly produced an immediate and striking improvement maintained for the next two periods of 3 months. The second case was an adult of 44 years weighing 17 kgm. in wretched condition suffering not only from kala-azar but also from pulmonary and peritoneal tuberculosis and an intercurrent catarrhal pancreatitis. The drug was given in smaller doses and for a longer time than in the first case. There was some improvement but parities could still be seen at the end of treatment. It developed measles with an intense laryngitis and died.

The authors conclude by stating that a non-toxic antimonial like 168 R.P. should be given in massive doses and in a short course of treatment.

11 Most patients treated so far by 2168 R P have been children, but an adult case is here reported in considerable detail. The patient was 20 years old, weighing 58 kgm, and had been seriously ill for 8 months. He was treated by 100 mgm per kgm daily (except for the first two doses which were rather less), to a total of 76.5 gm for the whole course. Results were excellent, over an observation period of two months, and the authors believe the patient to be cured. They write that all important references to previous use of this compound are given by R. SOHIER in the *Journal de Médecine de Lyon* for September 5th, 1947.

111 A brief paper, over the initials G. F., declares that 2168 R P is rapidly and completely eliminated in the urine. Methods of urine estimation are described.

HAZARIKA, A. N. Treatment of Kala-Azar with Pentamidine Isothionate. A Study of 55 Cases. *Indian Med Gaz* 1949, Apr., v 84, No 4, 140-45

A series of 55 Indian patients were treated for kala azar, with pentamidine isethionate [incorrectly referred to throughout as isothionate]. In each case the diagnosis was confirmed by the finding of leishmania by spleen puncture. Of the 55 patients 34 were antimony-resistant. The drug was given daily in a 10 per cent solution, intravenously in 25 cases, intramuscularly in 28, and by both methods in the remaining two cases. The maximum daily dose was based on the weight of the patient, in 19 cases this was 1.0 mgm per pound weight of patient and in 32 it was 1.5 mgm, in the other 4 it was just outside this range. To obviate toxic reactions, the initial doses were usually less than this maximum. Ten to twenty injections were given to each patient and the total relative dose (per 100 lb weight of patient) ranged between 0.60 and 3.00 grammes.

The immediate reactions to intravenous injections were the vasomotor symptoms usually associated with the 4'-diamidine drugs but they were not severe, except in one case and there were no late sequelae such as the neuropathies associated with stilbamidine. There were no immediate reactions after intramuscular injections. However, 4 patients developed oedema during or after treatment.

Three patients died and one absconded. The rest were clinically cured at the time of discharge—immediate cure rate 94.44 per cent. In a follow-up investigation, it was found that 6 months after the completion of the course 16 of the 42 followed up had relapsed, a relapse rate of 38.09 per cent.

The relapse rate among antimony-resistant cases was 33.33 and among the remainder 50.00 per cent. There was little difference in the relapse rate between those receiving 1.0 mgm and those receiving 1.5 mgm of the drug per pound weight, the figures were 46.6 per cent and 34.78 per cent, respectively.

It is suggested that in view of the absence of toxic symptoms larger dosages might be employed.

RIS H & FOX, J. P. The Cytology of Rickettsiae. *J. Exper. Med.* 1943 June 1 v. 89 No. 6 681-5 1 text fig. & 17 figs. on 7 pls. (14 r. 16.)

The authors describe a series of studies in which highly specialized technical methods were employed, including the use of the phase-contrast and the electron microscope. Twelve excellent photographs, most of which were taken with these microscopes, show that *Rickettsia prowazekii* has a physical structure of the same type as most bacteria: their "nuclear structures" or "chromatinic bodies" are sharply defined minute spheres which are single in spherical forms of rickettsiae and vary in number from two to four in rod-shaped rickettsiae; occasional dumb-bell forms occur; these are probably undergoing nuclear division.

By special cytochemical and staining methods the authors have found evidence to show that the nuclear structures like those of bacteria, contain desoxyribonucleic acid as well as ribonucleic acid, whereas some previous workers have concluded that rickettsiae resemble viruses in containing only one type of nucleic acid.

ZAHARIA, N. I. & DIMITRIU, A. Les réticulocytes au cours du typhus exanthématique. (The Reticulocytes in Typhus Fever.) *Arch. Roumaines Path. Expt. et Microbiol.* 1943, v. 15 No. 1/2, 101-11 graphs.

The author gives a summary of modern views on the significance of changes observed in the number and type of reticulocytes during the progress of certain diseases.

In 25 typhus patients an irregularly progressive diminution occurred in the number of the reticulocytes after the 3rd or 4th day; in some cases there was a total disappearance of the reticulocytes during the second week. There was a return to the normal number during convalescence. The diminution was most pronounced in the old reticulocytes so that the formula showed deviation to the left, followed in the 3rd and 4th weeks by a slight deviation to the right.

The reticulocytopenia was regarded as being due to damage caused to the bone marrow by the typhus toxin.

COMBESCO, D., DIMITRISCO, N. & CORJESCO-MANCIULESCU, E. Mme. Recherches sur le typhus exanthématique. L'influence de la splénectomie sur la réceptivité des animaux de laboratoire à l'infection expérimentale-typhique. (The Influence of Splenectomy on the Susceptibility of Animals to Experimental Typhus Infection.) *Arch. Roumaines Path. Expt. et Microbiol.* 1943 v. 15 No. 1/2, 91-103 13 charts.

The spleens of five guinea-pigs were removed at periods ranging from 30 to 138 days after experimental attacks of typhus fever. Four to ten days after the operation the animals were challenged by a second inoculation with typhus infection. Four reacted in the same way as normal control guinea-pigs and one was immune.

In similar experiments on five rabbits it was found that two had lost their immunity after splenectomy and three did not react to the challenge of reinoculation.

John W. D. Meigs

COMBIESCO, D, DUMITRESCO, N, STURDZA, Nina & BOTEZ, V, Mme, with the collaboration of C POPESCO, G PANAITESCO & C ZILISTEANU Recherches sur le typhus exanthématique Étude sur l'immunité acquise Efficacité comparative de trois vaccins tués Propriétés sérologiques des sujets vaccinés [A Serological Study of the Immunity caused by three Killed Typhus Vaccines] *Arch Roumaines Path Expér et Microbiol* 1948, v 15, Nos 1/2, 68-90, 4 graphs & 1 fig [23 refs]

Tests were carried out at fixed intervals on the sera of three groups of 24-25 men vaccinated with a yolk-sac, a mouse-lung, and a dog-lung typhus vaccine respectively The number of *Rickettsia prowazekii* in each type of vaccine was approximately the same

No significant difference in the antigenic activity of the three vaccines was observed

In the combined results of Weil-Felix tests the percentages of positive reactions at titres of 1-100 to 1-250 were —before vaccination, 27, thirty days after vaccination, 67.2, sixty days after vaccination, 40.0, and ninety days after vaccination, 2.3 In 20 per cent of the cases the reaction remained negative at 1-50 throughout the period

With the Kudicke and Steuer dry-blood rapid agglutination test [see this *Bulletin*, 1943, v 40, 898] negative reactions were always obtained, though this test was always positive in cases of typhus in which the Weil-Felix titre was higher than 1-250

The intradermal rabbit test of Giroud was carried out on sera of 46 of the men, in six cases there was some degree of "neutralizing power" before vaccination, in 33 a considerable degree of neutralizing power was acquired after vaccination, and in two the reaction was moderately positive before and after vaccination No significant difference was observed in the responses observed after vaccination with the three different vaccines There was no correlation between the results of the Giroud and the Weil-Felix tests, often one was positive and the other negative When both were positive the times of appearance of the reactions were different and the Weil-Felix reaction remained positive longer than the Giroud which always became negative before the 60th day The authors regard these results as being additional evidence that the protective antibodies are independent of the anti-proteus agglutinins

[The rapid disappearance of the antibodies concerned in the Giroud reaction suggests that they are not the substances responsible for giving durable protection against typhus fever]

DENT, J E, MORLAN, H B & HILL, E L Effects of DDT Dusting on Domestic Rats under Colony and Field Conditions *Pub Health Rep* Wash 1949, May 27, v 64, No 21, 666-71, 1 chart

A colony of rats was exposed to conditions similar to those occurring when DDT dust is used for the control of rat fleas By the end of three weeks 24 of the rats had died The liver and fat of the dead rats contained enough DDT to account for death Within 11 weeks, 36.3 per cent of the rats died, apparently of DDT poisoning, but it is stated that general field observations indicate that this rate is in excess of what can be expected under conditions in which the rats have greater opportunities of avoiding contact with the dust

No mention is made of the occurrence of births in the colony which consisted originally of 43 male, 50 female, and 20 baby rats The only comment on the effect of the procedure on the rat population is the statement that DDT dusting "affected this directly"

DERICK, E. H. & BROWN H. E. Isolation of the Karp Strain of *Rickettsia tsutsugamushi*. *Lancet*. 1949 July 23 150-51 [17 refs.]

The Karp strain of *Rickettsia tsutsugamushi* (*R. orientalis*) well deserves a biographical note. It was isolated by the authors at Brisbane in January 1943 by inoculating a guinea-pig with the blood of an American soldier called Karp who had been infected in New Guinea before being evacuated to Australia. The guinea-pig had a sharp febrile attack which started 10 days after inoculation and the strain was readily passed through other guinea-pigs, none of which died during the first nine passages but thereafter about 50 per cent. of the inoculated guinea-pigs succumbed.

In its pathogenicity to the originally inoculated guinea-pig the strain differed from Malayan and other strains. It has been very extensively used in the experimental study of scrub typhus, for example in 1945 by such workers as TORRIS FULTON and JOYNER and BERTSON and since that time by many other workers.

It has been responsible for a considerable number of laboratory infections already noted in this *Bulletin* including the tragic fatal illness of Miss Dora LUSH at the Melbourne Laboratory in 1943.

SMITH C. N. COLE M. M. & GORCK H. H. Biology and Control of the American Dog Tick. *U.S. Dept. Agric. Tech. Bull. No. 803* Wash. 1949, 74 pp. 37 figs. [21 refs.]

DE MAGALHÃES O. Profilaxia do tifo exantemático neotrópico no Brasil. [Prevention of Neotropical Exanthematic Typhus in Brazil.] *Rev. Hig. e Saú. P&M* 1949, Apr.-Dec. v. 8 Nos. 2, 3 & 4 169-78.

The author describes the measures needed for the control of tick borne typhus in Brazil. He refers to the bed-bug as being a transmitting vector in addition to the ticks *Amblyomma cajennense* and *A. latense*. The method of control recommended are—destruction of the vector arthropods and of animals known to be reservoirs of infection especially dogs and goats, propaganda by cinema, posters, leaflets and lectures and vaccination by yolk-sac vaccines.

It is suggested that in addition to the very severe cases which special attention has been paid there are also mild and even inapparent attack during "silent" periods and in areas in which the disease is not detected. The mild attacks may be caused by transmission by bed-bugs or by strains of rickettsiae of low virulence transmitted by ticks. It is believed that in certain areas the population has been immunized by these mild attacks so it is doubtful whether yearly vaccination would be of sufficient value to justify the maintenance of an expensive organization.

COMBIESCO, D, DUMITRESCO, N, STURDZA, Nina, BOTEZ, V, Mme, CIUREA, V & ZARNEA, G Recherches expérimentales sur la nouvelle rickettsiose isolée en Roumanie [Investigations into the New Rickettsial Disease [Q Fever] of Rumania] *Arch Roumaines Path Expér et Microbiol* 1948, v 15, Nos 1/2, 242-4

The author describes briefly the reactions produced in guineapigs inoculated with the strain of *Rickettsia burneti* isolated from Q fever patients in Rumania.

The rickettsia survived in guineapigs up to 64 days. None of the 50 guineapigs employed in the course of 14 transfers died. The chief lesions found in guineapigs sacrificed on the 4th day of the fever were great enlargement of the spleen and extensive congestion with mononuclear-cell infiltration of the interalveolar tissues of the lungs.

COMBIESCO, D, COMBIESCO, Cornelia, DUMITRESCO, N, POPESCO, C & ZARNEA, G Diagnostic rétrospectif par la réaction de fixation du complément, d'un nouveau foyer de la maladie provoquée par la nouvelle rickettsiose identifiée en Roumanie [Retrospective Diagnosis of a New Focus of Q fever in Rumania] *Arch Roumaines Path Expér et Microbiol* 1948, v 15, Nos 1/2, 264-5

See this *Bulletin*, 1949, v. 46, 627.

COMBIESCO, D, DUMITRESCO, N, BOTEZ, V, Mme, STURDZA, Nina & ZARNEA, G Infections de laboratoire avec la nouvelle rickettsiose isolée en Roumanie [Laboratory Infection with the New Rickettsial Disease [Q Fever] of Rumania.] *Arch Roumaines Path Expér et Microbiol* 1948, v 15, Nos 1/2, 244-7

Three of the workers engaged in the manipulation of material infected with *Rickettsia burneti* suffered from attacks of Q fever. The diagnosis was confirmed by complement-fixation tests in which an Australian and a local antigen were used.

Infection was believed to have been acquired by the inhalation of infected droplets.

John W D Megaw

WOLFE, D M & KORNFIELD, Lottie The Application of a Quantitative Complement-Fixation Method to a Study of Q Fever Strain Differentiation *J Immunology* 1949, Apr, v 61, No 4, 297-306 [18 refs]

Several workers have observed disconcerting differences in the complement-fixing antigens of various strains of Q fever rickettsiae [see this *Bulletin*, 1949, v 46, 726].

The authors found that when fixation tests were carried out in the usual way, by the "serum dilution" or "antigen dilution" method, the reactions with the American (Dyer) strain of antigen were at much lower titres than those obtained with the Italian (Henzerling) or the Australian strain.

A series of tests was made with the quantitative complement-fixation technique developed by the Division of Laboratories and Research of the New York State Department of Health. The technique is much too complicated for general use, the underlying principle is that all reactions are evaluated in terms of the amount of complement needed for 50 per cent haemolysis [see this *Bulletin*, 1946, v 43, 210, and 1947, v 44, 654].

Twenty sera of persons infected in America, Italy, Germany, and Switzerland were tested and the titres observed were not significantly different in any serum irrespective of whether the antigen used was of American or Italian origin.

John W D Megaw

CALVERT J. F. A Preliminary Report of a Search for Q Fever in New Zealand
New Zealand Med J 1949 Apr., v 48 No 264 174-9. (16 refs.)

No evidence of Q fever infection was found in any of four patients treated at the Auckland hospital for primary atypical pneumonia. Blood from three of the patients taken at the height of the fever was inoculated intraperitoneally into guinea-pigs with negative results, and the sera of the patients, examined 23 to 47 days after the attack gave negative reactions to agglutination tests against *Rickettsia burnetii*.

Agglutination tests carried out on 11 abattoir workers and 17 dairy farmers in places where *H. emphyzal. hispaniae* was common, also gave negative results.
 John H. D. Meyer

BOWER A. G. Q Fever. *Arizona M J* 1949 May v 6, No. 5 30-33. (31 refs.)

The clinical features of Q fever in California are briefly described. Pulmonary lesions occur in 80 per cent. of the cases and in these differentiation from primary atypical pneumonia is impossible on purely clinical grounds though early and frequent chills are in favour of Q fever.

The severity ranges from mild ambulatory attacks in which the patient feels ill for one or two days, to a prolonged severe illness needing hospital treatment for a month or more. The average duration is 7 to 11 days.

Streptomycin was effective in daily quantities of 2 to 3 gm. given intramuscularly in six divided doses during the febrile period, and in half these doses for the next two to four days.

Aureomycin is said to be specific. It is given by the mouth in total daily doses 150 mgm. per kgm. body weight but it is very costly at present.

Infection is believed to be acquired chiefly by inhaling infected dust from material contaminated by the urine or dung of cattle but drinking infected milk is also a mode of transmission.
 John H. D. Meyer

YELLOW FEVER

MAHAFFY A. F. The Epidemiology of Yellow Fever in Central Africa. *Trans Roy Soc Trop Med & Hyg* 1949 May v 42, No. 6 511-1. maps, 77 refs. Discussion 525-30. LINDLAY G. M. M. (in reply) J. F. MARGRAITH B. CARNHAM P. C. C. HACKETT C. J. RAY W. MORGAN M. T. MAHAFFY A. F. (in reply)

In 1936 a team of workers under Mahaffy commenced study of the epidemiology of yellow fever in Central Africa. In the course of the following 14 years this group has made many contributions to our knowledge of the subject and in addition has found at least eight new viruses.

Practically all the studies of Mahaffy and his colleagues were made in Bwamba County, Uganda which is a small heavily forested area. The main forest (Nemba) is known to be human habitation but about 35,000 people live in the cultivated zone between it and large areas of unraided Mijikenda country and man were all examined for virus and most of the results have been described in detail already in numerous papers which have been fully reported in this Bulletin.

The main point made by Mahaffy was that yellow fever never appeared to be primarily due to *S. f. f. f.* (the *A. f. f.*) in the forest. All attempts to isolate virus from these mosquitoes in the area

of their investigation were unsuccessful. Arboreal monkeys, however, raid the human plantations for food and may be bitten by *A. simpsoni* which then transmits the disease to man. *A. simpsoni* may on occasion also enter the forest for a blood meal and bite an infected monkey. Although *A. aegypti* occurs in this region it apparently plays no part in the cycle. The naturally infected monkeys seldom die and they travel only very short distances.

In discussion of Dr Mahaffy's paper it was mentioned that there was a lot of evidence which suggested that the forest type of the disease exists in West Africa and that monkeys play as important a part as vertebrate hosts but the forest vector has not yet been found in that region. Mahaffy said he regarded it as extremely unlikely that the control of either the animal host or the forest vector could be undertaken with any reasonable hope of success. Persons exposed to the sylvan type of the disease can, however, be protected against it by vaccination.

F O MacCallum

HOVANITZ, W. Comparisons of Mating Behavior, Growth Rate, and Factors Influencing Egg-hatching in South American *Haemagogus* Mosquitoes. *Physiol Zool* Chicago 1946, v 19 No 1 35-53, 5 figs [18 refs]

RABIES

JERVIS, G. A. & KOPROWSKI, H. Encephalomyelitis of possible Allergic Etiology in Mice Injected with Rabies Vaccine. *Canadian J Comp Med* 1949, May, v 13, No 5, 116-21, 3 figs [21 refs]

Occasionally paralysis of limbs has been observed in mice after vaccination with the Semple type of rabies vaccine. Thus, in the experiment described in the present article, 55 Swiss mice were employed in testing, by Habel's method, the potency of a phenolized, wholly inactivated, rabies vaccine, prepared from horse-brain tissue infected with rabbit-brain fixed virus, 2 animals developed a paralysis which, beginning in the posterior limbs, gradually extended to the anterior limbs.

In the paralysed mice, sacrificed one month after the appearance of first symptoms, the pathological lesions occurred almost exclusively in the white matter of the central nervous system as multiple, small areas of demyelination and perivascular infiltrations distributed throughout the spinal cord, cerebellum and midbrain, they were unlike those caused by mouse encephalomyelitis virus (typically inflammatory reactions localized in the grey matter, absence of demyelinating areas), but closely resembled those obtained in guinea-pigs after injection of rabbit brain with adjuvants. Inasmuch as the mice in the present study received inoculations of brain tissue without adjuvants however, the conditions of the experiment approximated to those in human subjects receiving repeated injections of rabies vaccine, even if the total dosage per kilogramme of body weight in mice was 25 times that in man.

In their summary the authors suggest that the lesions found in the paralysed mice may have been due to an allergic reaction to an antigen in the horse-brain tissue present in the rabies vaccine. The similarity of this pathological picture to that previously described in the guinea-pig under similar experimental conditions is stressed and its bearing on post-vaccinal encephalitis in human subjects receiving anti-rabies treatment is indicated.

G Stuart

PLAGUE

SEAL, S. C. Pneumonic Plague Cases in Calcutta and Gaya. *Indian Med Gaz* 1949 Apr v 84 No. 4 162-70 1 fig & 2 charts. [15 refs.]

Between March 25th and April 7th, 1949 twelve members of a family community of 31 persons were attacked with pneumonic plague and two other persons who had come into close contact with the patients were also attacked. Only one of the patients survived—he was treated with streptomycin in a Calcutta hospital.

Infection was introduced by a member of the family who had arrived from a plague infected locality on the day of onset of his illness. Four days later two attacks occurred and during the following three days there were seven more cases. After an interval of three days the remaining four patients were attacked within a period of three days. No further cases occurred although large numbers of persons came into close contact with several of the patients attacked during the latter stage of the outbreak—some of these patients had fled from the infected household during the incubation period and others were admitted to hospitals where the nature of their illness was not at first recognized.

The incubation period was usually about two days—death occurred in most of the cases within two or three days—in two cases the patients died after an illness of five days. Signs of lung involvement were not striking there was little sputum and this was blood-stained in only one case.

A brief reference is made to another outbreak at Gaya, Bihar in which a homoeopathic doctor became infected while attending a group of six patients who had become infected in a distant locality where plague was occurring. Ten members of the doctor's family of 18 persons were attacked and died in rapid succession.

These outbreaks were typical of plague pneumonia as it occurs in India. The author quotes the records of nine outbreaks which occurred in Eastern Bengal between 1898 and 1911—the number of cases ranged from 4 to 51 and all but one was in a locality where plague had not occurred. The 1st in Plague Commission of 1908 is quoted as stating that only about 30 per cent of the cases of plague in India were of the pneumonic type.

[The rapid and spontaneous termination of these dramatic outbreaks suggests that when infection is transmitted from man to man by droplet infection the organisms soon lose their virulence. Another interesting feature of plague pneumonia is that although many outbreaks have occurred in plague free areas there is no record of the establishment of infection among the rats of the affected localities. In India at any rate the outbreak though tragic appears to be self-limited and to be of little epidemiological importance.]

John H. D. Menzies

POLLITZER, R. Recent Trends in the Treatment and Control of Plague. *Acta Tropica*. Basle 1949 6 No. 1 30-40. 23 refs.

This is a valuable critical summary of recent advances in connexion with the treatment and control of plague. In treatment the sulphonamides have proved their value—sulphadiazine and sulpham-razine are specially recommended because they can be given intravenously in severe cases.

Streptomycin given alone or as a supplement to sulphonamide treatment has given still better results. Serum can be expected to add to the efficacy of the treatment especially if the new purified rabbit serum can be made available. The above lines of treatment may save the lives of some pneumonic plague patients.

Great importance is attached to the use of sulphonamides as prophylactics for persons who have come in contact with patients suffering from pneumonic plague, but the method is not recommended for general use in bubonic plague. Killed vaccines are of undoubted value, especially when the two-dose method is adopted and booster doses are given later when risk of infection persists. Living attenuated vaccines may become suitable for general use if they can be made available in stable, lyophilized, form, so also may purified crystalline antigens.

Flea control by DDT, and inoculation, are the methods of control most generally applicable in the presence of infection. The elimination of rats is the ideal method of long-term control.

Treatment of patients in their own homes or in village emergency hospitals should be far more widely carried out than is the case at present.

RUEGSEGGER, J M & GILCHRIST, H. The Present Outlook in Plague. *Indian Med Gaz* 1949, Apr, v 84, No 4, 159-61 [22 refs]

This article is on the same lines as the above, but the authors have not had the advantage of personal experience in the field.

A prediction is made that when more potent and less expensive antibiotics become available plague vaccines will lose their popularity.

[In reaching this opinion the authors have probably been influenced by certain recent reports which are regarded by most experts as having conveyed an unduly pessimistic impression of the efficacy of vaccines.]

CHOLERA

- 1 BROUNST, G & MAROUN, T. Recherche d'anticorps chez des sujets vaccinés contre le choléra [Agglutinin Levels after Inoculation against Cholera] *Ann Inst Pasteur* 1949, June, v 76, No 6, 554-7
- 11 GALLUT, J & BROUNST, G. Sur la mise en évidence des agglutinines cholériques [Demonstration of Agglutinins in Cholera] *Ibid*, 557-9

1 The agglutinin levels produced by inoculation with anti-cholera vaccine were determined in 486 military subjects. A first series of sera was taken from 371 subjects 20 to 60 days after inoculation with a single dose of a vaccine containing equal parts of Inaba- and Ogawa-type strains at a total dosage of 2,000 million vibrios. The tests were made against suspensions of *V. cholerae* in 0.2 per cent formal-saline. Of the 371 sera, 365 were negative at a dilution of 1 in 25. 6 (1.6 per cent) were positive at dilutions of 1 in 25 to 1 in 100 only.

A second series of tests was made on sera of 95 subjects who, in addition to the initial dose of 2,000 million vibrios, received two additional doses of the vaccine bringing the total to 14,000 million. At the same period after inoculation, 84 sera gave negative results and 11 (11.5 per cent) were positive at dilutions of 1 in 25 to 1 in 100.

In view of the mediocre results obtained in the above tests live suspensions of *V. cholerae* were used for tests of a third series of 20 sera of persons given the same course of inoculation as the second series. Of these 13 were negative and 7 (35 per cent) were positive at 1 in 25 to 1 in 200.

Local reaction to intradermal injection of 0.1 cc. of anti-cholera vaccine was tested in 10 immunized subjects. 5 showed redness and swelling of some degree with or without a zone of necrosis or palpable nodule at the site of the injection.

The results are considered to show that the production of agglutinins in persons inoculated with anti-cholera vaccine is exceptional and less frequent than is generally supposed. The use of formalinized suspensions for the test will reduce the number of positives obtained. The test for intradermal reactivity may be useful for demonstrating evidence of immunity.

i. Following on the work reported above a comparison was made in more detail of the results of agglutination tests with living and formalinized suspensions of *V. cholerae*. The living suspensions were used fresh and the formalinized after being kept for 24 hours and for 7 days. The sera of 18 persons inoculated with the same total of 14,000 million vibrios were examined. Against live Inaba suspensions 8 were negative, 8 positive (1 in 20, 1 positive at 1 in 50, 2 positive at 1 in 100 and 1 positive at 1 in 500). Against live Ogawa suspensions 4 were negative, 8 positive at 1 in 50, 7 positive at 1 in 20 and 1 positive at 1 in 500. With formalinized suspensions kept 24 hours before use only 3 gave positive results with the Inaba strain and with the Ogawa strain, the titres being 1 in 20 to 1 in 50. When the suspensions were kept 7 days before use two only gave positive results with Inaba and one with Ogawa suspension, at the same low levels.

Additional tests were carried out with anti-O cholera diagnostic sera prepared in rabbits and showing titres of 1 in 10,000 with the homologous type strain, when living suspensions were employed. Titres with formalinized suspensions were only about one-quarter of those obtained with living suspensions.

The authors conclude that it is essential to use live suspensions for agglutination tests on the sera of inoculated persons, for the purpose of demonstrating the presence of antibodies, on account of the very low titre usually reached.

[This is the usual method employed by experienced cholera workers.]

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

ADAMS A. R. D. & SEATON D. R. Amoebiasis in England as a Household Disease. *Brit Med J* 1949 July 16 131.

Isolated cases of a toxithonous amoebic infection have been recorded in Britain, but for the most part without regard to the source of infection or of infectivity to contacts. The authors now report three families in Liverpool in each of which more than one member was suffering from amoebiasis. The original cases were seen in July 1947, July 1948 and February 1949 respectively.

The first case was that of a ship officer who had had proved amoebic dysentery for a few weeks. His wife, who had not been overseas, had recently developed diarrhoea and examination of her stools showed that she had active amoebic dysentery.

The second case was in a boy (16 yr) who had undetermined dysentery intermittently for 1 year. Numerous very faint *E. histolytica* were found in the stools. He had been all his life in Liverpool slum. In all the other members of his family. The boy's mother had had diarrhoea for two months and stool examination showed that she had acute amoebic dysentery. The

stepfather and four of the six other children were passing *E histolytica* cysts, but were in good health. The family was also largely infected with *E coli*, *Giardia* and threadworms.

The last case was that of a boy of 7 with an intractable colitis for three years. Very large numbers of vegetative *E histolytica* were found in the stools. He had never lived out of Liverpool. Stools from five other members of the family were negative, except those of his stepfather who was passing *E histolytica* cysts. He had no history of dysentery but had been in India until he was 13 (he is now 45) and had lived in England ever since.

The authors point out that these experiences are a reminder that amoebiasis may easily spread in households where personal cleanliness is not high. They stress the necessity of excluding amoebic dysentery by microscopic examination before ulcerative colitis is diagnosed. The possibility of the former condition being present is not perhaps considered sufficiently in Britain, yet two of the patients referred to above had been ill for years and were in poor health for want of proper diagnosis which earlier microscopic examination would have readily provided.

H J O'D Burke-Gaffney

GAEHLINGER, H. La dysenterie ambiennne, maladie d'association parasitaire et microbienne [Amoebic Dysentery as a Combined Parasitic and Bacterial Disease] *Bruxelles-Méd* 1949, June 5, v 29, No 23, 1255-60.

Some authors attribute the pathogenicity of *Entamoeba histolytica* solely to the parasite, others consider it dependent on an association with certain bacterial concomitants. The author, on the evidence, considers it certain that amoebic dysenteric manifestations are aggravated by concurrent bacterial infections. Reviewing the history of the treatment of amoebic dysentery he refers to the failure of emetine to sterilize the infection, and he considers that drugs like the iodoquinolines, rivanol, benzo-metacresol and the pentavalent arsenicals, all of which exert some amoebicidal action, have an antiseptic action. Emetine itself is not only an amoebicide but it promotes the agglutination and phagocytosis of pyogenic micro-organisms. These facts support the view that concomitant bacterial infections play their rôle in determining the pathogenicity of an amoebic infestation, and the remarkable success of the emetine-penicillin-sulphaguanidine treatment of severe amoebiasis confirms this. There is no evidence, the author suggests, that non-pathogenic strains of *E histolytica* exist, or of the existence of *E dispar* as a separate species. The apparently non-pathogenic strains of amoebae rapidly become pathogenic in a suitable bacterial environment. The conditions for this are prevalent in the human bowel in hot moist countries, and less so in cold temperate climates.

A R D Adams

PIPKIN, A C. Experimental Studies on the Role of Filth Flies in the Transmission of *Entamoeba histolytica*. *Amer J Hyg* 1949, May, v 49, No 3, 255-75 [26 refs.]

The author re-examines the role of flies as disseminators of *Entamoeba histolytica*, the causative organism of amoebic dysentery. Instructive results are obtained by a comparison of the ability of *Musca domestica*, *Lucilia pallens*, *Cochliomyia macellaria*, *Phormia regina* and *Sarcophaga musera* var *sarracenoides* to carry cysts and vegetative forms on the external parts of the body, in the crop, midgut and hindgut, or to deposit them in the vomit or in the faecal drops. At various intervals after clean, laboratory-bred flies of each species had fed on a highly infected faecal pabulum, direct observations were made

on washings or on dissections of the flies and a parallel series of cultures were set up from the same material. Vomit drops and faecal drops were taken up in micropipettes and examined by similar means.

Culturable trophozoites did not persist on the external surfaces of flies for more than 15 minutes after contact with infected material. Trophozoites were, however, culturable after 40 minutes in the crop and 30 minutes in the midgut but none were cultured from the rectum although they were seen by direct observation in this region 10 minutes after the meal.

Cysts survived longer than the trophozoites. On the external parts of the body they persisted in culturable form for up to 4 minutes and for as long as 210 minutes in the crop, 740 minutes in the midgut and 10 minutes in the rectum.

In the vomit drop, trophozoites were obtained in culturable form for up to 17 minutes and culturable cysts for 64 minutes after the infecting meal. Faecal drops contained culturable cysts for as long as 234 minutes.

Detailed figures are provided in elaborate tables and a comprehensive statistical analysis of the data shows that there is, in fact, a tendency for both trophozoites and cysts to survive longer in the crop than in the midgut or rectum of all the species of fly. This amoebicidal effect apparent only in the midgut and rectal region of the flies was not more marked in one species than in another. Cysts survived the passage through the gut better than did the trophozoites.

The number of flies vomiting infective drops was substantially the same for each species. On the other hand, the total number of infective vomit drops varied significantly with the species: the larger species continued to vomit culturable cysts for longer periods than the smaller species. This is attributed to the larger capacity of the crop of the larger flies. There was however, less evidence to suggest that the length of the gut affected the length of time during which infective faeces could be deposited.

It is concluded that the passage by flies of viable cysts in their vomit drops and in their faeces are the two most likely methods by which they could play a part in the spread of amoebic dysentery. External carriage of any form of the amoeba and the deposition of trophozoites in the vomit or in the faeces are considered to be mechanisms of minor importance.

D. S. Hertram

ORTIZAR E. R. & MONTERO O. L. *Amoebiasis crónica y apendicitis*. [Chronic Amoebiasis and Appendicitis.] *Rev. Med. Chile* 1949 76 77 N. 105-106, 5 figs. 27 refs.]

The authors point out how often the appendix may be invaded by *E. histolytica* and quote the figures given by Laut 1936 in which the appendix came a close second to the caecum—the 41st most in 1st, 3rd and 33.3 per cent, respectively. They relate details of few known examples where the diagnosis was by no means easy and the symptoms were those of appendicitis, acute or chronic, and in one the operation of appendectomy was undertaken. Diagnosis may need the help of a detailed study of the history, rectoscopy, faecal examination, complement fixation and radiological examination after administration of a barium enema.

SMITH B. Two Cases of Amoebic Liver Abscess with Complications. *Ind. Med. Gaz.* 1949 Apr. 84 No. 4 147-B.

"The post-mortem findings of two cases of amoebic liver abscess with complications are described. Case 1 had no history of amoebic dysentery. The

abscess in the liver was situated on the posterior aspect of the left lobe. Pin-point amoebic ulcers were found in the upper part of the descending colon only. The liver showed a typical amoebic abscess but amoebae could not be demonstrated in histological sections. The abscess in the lung as well as the pin-point ulcers in the descending colon showed amoebae in large numbers. Case 2 was admitted to hospital with amoebic dysentery. At autopsy no dysenteric ulceration of the gut was to be seen. He had an encysted liver abscess as well as an encysted abscess of the spleen, abscess of the lung and a cerebral abscess showing secondary infection. No amoebae could be demonstrated in any of the abscesses."

DAVIS, F W, Jr. *Amoebiasis. Experience in the Johns Hopkins Hospital, 1936-1946. Amer J Med Sci* 1949, May, v 217, No 5, 505-17 [50 refs]

Between 1936 and 1946, 296 in-patients at the Johns Hopkins Hospital were said to suffer from amoebiasis, of these only 205 were diagnosed parasitologically, and these accounted for 0.51 per cent of all admissions to the medical wards during this period. The author has analysed the data relevant to these cases in the light of the considerable literature on the subject. The protean nature of the symptomatology and physical findings in amoebiasis is re-emphasized, diarrhoea and abdominal tenderness proved the most constant features. The iodoquinoline compounds are advocated in the treatment of uncomplicated amoebiasis, emetine being reserved for severe cases and those with extra-intestinal involvement. In resistant cases combinations of drugs may be used, but the preparations employed are of less consequence than their administration for an adequate period. Twenty-five per cent of the patients continued to suffer from symptoms after treatment, although the stools no longer contained parasites, a true post-amoebic ulcerative colitis developed in only 5.9 per cent of the cases.

[This paper covers a wide field and gives a restrained and well-balanced account of the subject, it should be consulted in the original by those interested.]
A R D Adams

MALHOTRA, S L. *Causes of Failure in Treatment of Amoebic Dysentery. Indian Med Gaz* 1949, Mar, v 84, No 3, 96-8

In spite of improved methods resulting from war experience, the apparent cure-rate after treatment of amoebiasis in India, where the infection is very prevalent, is still unsatisfactory. Possible reasons for this are examined and the author suggests that in re-infection from the faecally contaminated fingers of the patient or from those of carriers in the household, and not in persistence of the infection, lies the real explanation.
A R D Adams

BROUGHTON, N, OGILVIE, A C F & WYLIE, W D. *Diagnosis and Treatment in Latent Amoebiasis with special reference to Cases presenting with Pyrexia alone. J Trop Med & Hyg* 1949, June, v 52, No 6, 112-20

The authors observed 676 cases of amoebiasis in Aden between February and November 1947, most of these were free from symptoms. The diagnosis was based on recovery of the parasite by stool examination before or "after a provocative dose of emetine with or without purgation", sigmoidoscopy was a routine unless refused by the patient, but infection was detected solely by this means in only three cases. The clinical and pathological findings are discussed in some detail as the authors were impressed by their mildness or

absence in so many cases an aspect of amoebiasis to which they believe inadequate attention is directed in the textbooks. They consider stool re-examination is desirable for all persons returning from the highly endemic areas to the United Kingdom as carriers ("symptomless cases") all have lesions in the gut they need treatment both for the sake of themselves and to prevent dissemination of the infection to others. The treatment given by the authors followed conventional lines.

DO PRADO, F. C. Tratamento da amebíase. (Treatment of Amoebiasis.) *Hospital, Rio de Janeiro*. 1947 Mar., v. 31 No. 3, 431-40. English summary

After preliminary remarks on the various drugs employed in the treatment of infection by *E. histolytica*—emetine hydrochloride, enterovioform, yatrien carbamate, enterovioranol, etc., and adjuvant drugs such as sulphaguanidine, bacteriophages, vaccines and care in diet—the author refers to 140 selected cases of his own which he treated with iodine preparations (iodoquinoline) and pentavalent arsenicals in alternate weeks for a total of four months. He followed them up for a year or more and groups the results as follows: 98 were cured, amoebae were no longer found and the clinical symptoms cleared up; 24 still had attacks of diarrhoea or intestinal disturbance although the amoebae could no longer be found. The remaining 18 presented signs of a more or less chronic colitis with relapses or exacerbations, such as general depression, easy fatigue, transitory pain in the liver region, intolerance of certain foods, although faecal examination failed to reveal any entamoebae.

KNOTT, ALVA A. & MILLER, JEANNE. Comparative Studies on the Iodine Absorption of Anayodin, Chiniolon, Diiodoquin, and Vioform in Man. *Ann. Intern. Med.* 1949 June, v. 32, No. 6 1180-87 1 fig. 11 refs.

All these substances are iso-hydroxyquinolines. Anayodin—the same as chiniolon (also known as quinoxal) and yatrien! Distinguished from chiniolon by absence of the sulphonic acid group, diiodoquin has two iodine substituents, while vioform has one iodine and one chlorine.

Since direct methods of assay of these drugs are not available, their absorption after oral treatment was studied indirectly by determining blood iodine levels. The studies involving a total of 280 estimations were made on 76 patients under ambulatory treatment for amoebiasis, the treatment being the usual therapeutic dosage administered daily. In 10 cases peak blood concentration was reached before the 24th day of treatment and there was no evidence of cumulative absorption or toxicity. The recommended

therapeutic dosage of diodoquin gives the highest iodine blood levels, anayodin and chiniofon the lowest, while vioform gives intermediate values. However if absorbability be measured by relating the blood levels to iodine intake, then vioform ranks highest, diodoquin second, and anayodin and chiniofon third.

Evidently none of these compounds is wholly non-absorbable, as has previously been stated in connexion with diodoquin, and the fact that "reasonable" iodine blood levels are attained raises a question as to the effectiveness of these drugs on amoebae deep in the walls of the intestine or in other parts of the body. "If therapeutic value is dependent on iodine absorption, Diodoquin, Vioform and Anayodin or Chiniofon would rank in the order given in therapeutic effectiveness."

E M Lourie

GAN, K. H. Bijdrage tot de kennis van de amoeben bij ratten. [Contribution to the Knowledge of the Amoebae in Rats] *Med. Maandblad Batavia* 1919, Mar 1, v 2, No 3, 70-76 [12 refs.] English summary

The author describes two kinds of amoebae found in laboratory rats and in wild *Rattus rattus diardi*, in Batavia. One of these amoebae is said to resemble *Entamoeba histolytica*, while the other is *E. muris*. Both occur in the caecum of the rats.

In *E. muris* the ectoplasm is not clearly demarcated from the endoplasm and the movements are sluggish. Its general appearance is like that of *E. coli*, but, according to the author, it can be distinguished from the latter (1) by the smaller size of its cysts, and (2) by the structure of its nucleus, in which the peripheral chromatin granules are arranged in the form of a complete ring instead of an interrupted ring. The author saw only binucleate cysts with a large glycogen vacuole in *E. muris*.

The *histolytica*-like *entamoeba* is active, its pseudopodia are protruded rapidly and the ectoplasm is clearly separated from the endoplasm. The nucleus is conspicuous in unstained amoebae, and in stained preparations the peripheral chromatin granules appear in the form of an interrupted ring, which is said to be a characteristic of *E. histolytica* while the karyosome [the author's "chromatin mass"] may be central or eccentric. Only binucleate cysts were seen, in which there was a large vacuole displacing the nuclei to the periphery.

The food vacuoles in both amoebae contained bacteria. On addition of rat blood to samples of faeces containing the amoebae, the *histolytica*-like form readily ingested erythrocytes, whereas *E. muris* was less inclined to do so. Attempts to infect kittens with both kinds of the rat amoebae were unsuccessful. The paper is illustrated by photomicrographs and schematic figures illustrating the two types of *entamoeba* seen in rats.

The characters adduced for the *histolytica*-like amoeba, especially its nuclear structure and cysts, are not peculiar to *E. histolytica*, the presence of which in the author's material is therefore somewhat doubtful. It is more probable that both the amoebae described in this paper represent *E. muris*.

COUTIN, I., COCHET, G. & BICLET, J. Fréquence du parasitisme à *Giardia intestinalis* chez les enfants âgés de deux à six ans de la région du Nord. Frequency of *Giardia intestinalis* Infection in Children of Two to Six Years in the North of France. *Bull. Soc. Path. Exot.* 1949, v 12, Nos 3/4, 103-6.

Sixty-nine stool examinations, 5403 in all, were made in specimens from 1915 apparently healthy children in kindergarten schools in the Nord region.

Among these 629 (37.84 per cent.) harboured *Giardia intestinalis*; this incidence is one of the highest recorded among children in temperate regions.

H J O'D Burke-Gaffney

SIRKER, M. U. Two Atypical Cases of *Giardia* Infection. *Indian Med Gaz.* 1949 Mar., v 84 No. 3 103.

The first of these patients was a Muslim adult who had continuous pain around the umbilicus for three years. He had some anæmia and his general health had deteriorated. Treatment for chronic dysentery was ineffective. No parasites were found in the blood or stools other than *Giardia* cysts which were present on three consecutive daily examinations. Mepacrine in three courses at an interval of two weeks [dosage not stated] resulted in uninterrupted improvement.

The second patient was a child of seven with bronchial asthma, without eosinophilia. His liver was enlarged one inch below the costal margin. The general health was not affected. Treatment for asthma was ineffective. As the patient used to have one or two loose stools before the paroxysms of asthma the stools were examined. *Giardia* cysts were numerous; there were no other parasites found in the stools or in the blood. A similar course of mepacrine was given: no attacks of asthma have occurred for several months and the enlargement of the liver has diminished.

RITA G. & LEVI DELLA VIDA, B. Coccidio umana da *Isofovea* (nel di cui caso osservato a Roma.) [A Case of Human Coccidiosis in Rome] *Riv. d. Pat. Assit.* Rome 1949 June v 10 No. 2 117-119 figs. English summary (3 lines)

Infection of man by *Isofovea belli* is not common: the case reported here is only the fourth so far noted in Italy, previous ones being by SANGIORGIO in 1918 (this *Bulletin* 1919 17-22) and by FRANCHINI in 1927 *ibid.* 1928, v 25 733) and 1932. Infection is usually accompanied by some other parasitic protozoal or helminthic, and in the present instance by *Entamoeba histolytica* and *E. coli*.

The patient was an Englishman of 70 years resident for three years in Rome. He suffered from gastro-intestinal disturbance with diarrhoea, and faecal examination revealed cysts and vegetative forms of *E. histolytica* and *E. coli* and numerous oocysts of coccidia. Treatment with emetine brought about improvement of the symptoms and disappearance of the entamoebæ, but the coccidia could still be seen. It is difficult to say to what degree the symptoms were due to the *Isofovea*. Attempts to infect four guinea pigs and a monkey were not successful. The authors refer to the experimental infection of *Isofovea belli* in man reported in 1948 by M. R. S. B. and NORAWA [see this *Bulletin* 1949 v 46 261].

H. Harold Scott

HAWAWI, A. & EL HOKDY, M. I. The Incidence of Balantidiosis in Egypt with reference to the so-called Process of Budding in *Balan. d. m. coli*. *J. Roy. Egypt. Med. Ass.* 1948 Dec 31 v 1 836-40 1 fig.

According to previous record human balantidiosis is very uncommon in Egypt. The present authors have investigated its incidence and have encountered only 3 cases in the course of 11. In 1948. The examination of 70 specimens of stools (pieces slaughtered in the Cairo slaughter house) led to *Balan. d. m. coli* in 80 per cent. of the samples. They then turned their attention to pig breeders in the suburbs of Cairo. The total of 119 owners and members

of their families in one suburb were negative, while in another suburb a single case of infection with *Balantidium coli* was detected among 27 persons examined. The authors believe that "The rarity of balantidial infection in Egypt may be due to the fact that the great majority of Egyptians are Mahomedans who are not allowed to eat the meat of pigs, or to rear them."

The authors have successfully grown *Balantidium coli* in a medium consisting of serum (human, equine, bovine or ovine) diluted with buffered Ringer's solution in the proportion of 1 : 10, with the addition of a small amount of rice starch.

Both in cultures and in natural infections they found a few ciliates producing bud-like outgrowths varying in size. Since these "buds" revealed no nuclei when examined in stained preparations they are not regarded as a form of multiplication of *Balantidium* and their nature remains doubtful. This condition of "budding" is shown in a photo-micrograph. C A Hoare

LEPROSY

LEPROSY IN INDIA 1949, Apr., v 21, No 2, 39-121 All-India Leprosy Workers' Conference, Calcutta, 29th to 31st December, 1948

This voluminous number contains little new information, as the views of the principal authors had been recorded in papers shortly before at the Cuba Conference. The table of contents lists the names and speeches of politicians and others, but not the medical papers, so every page has to be turned over to find the latter. Fortunately the few points of interest are summarized in Part II and include the following. The subject of treatment was opened by COCHRANE, who has made an advance on his former advice to limit the use of sulphones to the most experienced workers by going to the other extreme of pushing large doses without any intermission during reactions, except very severe ones, in all lepromatous cases, but he does not advise sulphones in neural macules, tuberculoid or neural anaesthetic lesions for fear of causing them to become lepromatous. DHARMENDRA is unable to understand this limitation. S N CHATTERJEE advises the injection of small doses such as 3.5 per cent watery solutions of sulphetrone and diasone to a maximum of 5 cc, which produce clinical improvement without reactions or anaemia. These first two workers advise the combined use of sulphones and hydnocarpates [as advocated by the reviewer, see this *Bulletin*, 1948, v 45, 614]. MUIR differed from Cochrane in finding sulphones useful in tuberculoid cases. TEICHMANN recorded the after-results of hydnocarpates in 105 cases, almost all lepromatous ones. Large doses gave the best results with 27.3 per cent disease arrested for a time at least, but results as a whole were poor, although definite reduction in the incidence of deformity occurred.

The control of leprosy was discussed on the second day without bringing out any important new points. The third subject for discussion was the histopathology and classification of leprosy. This brought out great differences of opinion and a tendency to ever-increasing complication of nomenclature.

L Rogers

BLANCO, F L & FITE, G L. Silvering of *Leprosy* Bacilli in Tissues. *Arch Pathology* 1948, Dec., v 46, No 6, 542-9, 8 figs

This is an important paper, which should be read in original by all interested in the bacteriology of leprosy and for the elaborate method used which takes

about five weeks to carry out. The organisms are stained black and brown with differences of intensity. In the most highly active lesions, parallel columns of bacilli radiate from the centre of the containing cell and are never in bundles as with leishman. These are abundant young growing bacilli. In the more common chronic lepromata the spaces in the vacuolated cells are free from organisms, which tend to curve round them and show a greatly diminished rate of multiplication. Many of the bacilli in old globi become progressively more weakly silvered especially those centrally placed—these are considered to be degenerated forms without change in morphology which supports the idea that in old lesions death of the bacilli is constantly taking place. Pleomorphism of the lepra bacilli is only marked in chronic lesions. In silvered preparations clear narrow halos are seen around and separating the organisms. A new concept of the nature of the globus is thus offered. Good illustrations demonstrate the above points.

L. Rogers

KARX R. L., BARIBEAU Betty J & VILLALON Flora T. Universal Serologic Reaction with Lipid Antigen. IV. In Lepromatous Leprosy. *Amer J Clin Path.* 1949 May 1 19, No. 5 408-13 3 figs. (Summary appears also in *Bulletin of Hygiene*)

Sera from 55 patients suffering from lepromatous leprosy were examined by the Universal Serologic technique and typical results are shown in one table and three figures. Marked precipitation is noted before incubation and is strongest in the presence of reduced NaCl concentration—after 4 hours in the ice box almost all serum dilutions show precipitation—complete in zones I and III nearly complete in zone II—after 24 hours incubation all zones show complete precipitation. In contrast to the foregoing in tuberculo-leprosy there was no difference in precipitation after 4 and 24 hours incubation. It is suggested that in lepromatous leprosy there is not only an increase over the normal liberation of tissue lipid but also liberation of distinctive lipids—serological patterns vary with the activity of the disease—differing according as to whether it is active or burnt-out—these may serve to distinguish between different forms of the disease and as an index of response to treatment.

T. E. Osmond

LASSMAN P. Traitement de la lèpre humaine avec les produits traités de graines des *Ocoteles* du Congo Belge. ('Treatment of Leprosy with Extracts of Seeds of *Ocoteles* from the Belgian Congo.) *Ann Soc Belge de Med Trop.* 1949 31 r 31 v 29 No 1 23-R.

This brief note records a trial in the treatment of leprosy of an oil extracted from the seed of a species of *Ocoteles* such as that from Calcutta which was found by Dubois to be well tolerated in man (this *Bulletin* 1947 79 857) and actively to inhibit the growth of a human tubercle bacilli in cultures but whose chemical nature is unknown. Trials in cases mainly lepromatous men by infiltration of the cutaneous lesions including lepromata of the ear and also intramuscularly, in doses up to a total of 30 to 150 cc per case has resulted in clearing up of the skin lesions, and the method is equally effective in leprosy. As no general reactions or toxic symptoms resulted further trial are indicated although cures are not claimed.

L. Rogers

STAIGLI J & DIBIZ, O. Primeiros resultados obtidos com bogaalita no tratamento de leprocos em Minas Gerais. First Records of the Results of Treatment of Leprosy in Minas Gerais with Bogaalita. *Pan Am J Med Biol Sci.* São Paulo. 1948, Feb. July 19 No. 17 19 29 3 figs.

Bogaalita methanal formaldehyde sulphoxylate sodium has been tried in leprosy on the grounds that oxygen is necessary for growth of *M. leprae*.

and that a reducing agent will interfere with that growth. The authors refer to the 12 cases reported by FERNANDEZ and BERGEL [see above] and then speak of 8 cases of their own, all patients in an advanced lepromatous stage, 5 from the Santa Isabel Colony and 3 from the Roça Grande Sanatorium. They gave the drug, first in glucose saline, later in distilled water [strength not stated, but Fernandez and Bergel gave it in 10 per cent solution], starting with 1 gm daily (except on Sundays) for a week, then 1 gm night and morning, and increasing until in the fourth week 3.5 gm were given twice a day, and this was kept up to the end of 8 weeks. As others have found, if it is injected too quickly nausea and vomiting might occur.

The results were little or no change in the blood, no reduction of red cells, but usually some increase and maintenance of the haemoglobin value, the bacilli became fragmented and stained poorly, there was less nasal obstruction, less dysphonia, and improvement in the general health, with better appetite and sleeping. Lepromata softened and broke down. These changes are illustrated by photographs. [This drug is used also in leishmaniasis, see above, p 926]

[Development of Stefansky's Bacillus when inoculated on the Chorio-Allantoic Membrane of the Chick Embryo] *Ann Inst Pasteur* 1949 June, v 76 No 6 535-8, 3 figs

GOMES, J M. Ação do promin sobre o Mycobacterium de Stefansky. Estudos morfológicos. [Morphological Study of the Action of Promin on Stefansky's Bacillus] *Arquivos Facul de Hig e Saude Pública Univ de São Paulo* 1948, June, v 2, No 1, 19-30. English summary [13 refs]

The author started with 36 rats which he divided into three groups. (1) Controls, inoculated with a suspension of triturated leproma tissue. (2) Similarly inoculated, but promin treatment started a month later and after 9 weeks' treatment there was allowed one week free and the promin was then resumed for another 2 months, the drug being used in a strength of 1 per cent in milk. (3) As the last, but a month after resumption of treatment, the promin was stopped and carotenoid (1 cc of a 0.1 per cent colloidal suspension) injected three times each week. One month later, the carotenoid was suspended and promin again given for 10 days, after which all treatment was stopped. Some of the animals died but 16 lived for 4-6 months and were killed and examined. The controls showed a non-ulcerated leproma with bacilli, some smooth and short, others granular. The promin-treated animals (group 2), 6 in number, also showed a leproma locally in the right inguinal fossa, in one apparently normal, one necrosed, two with ulcers cicatrizing and in two the leproma was regressing and fibrosed, bacilli some long and smooth, others fragmented, some with dark granules and the organisms in globi. Those in group 3 showed fibrosed or ulcerated remnants of lepromata, in only one were there bacillary globi, the majority were fragmented and granular.

It is thought that the carotenoid stimulates the vitality of the bacteria, *in vitro* the colonies of acid-fast organisms grow more strongly, but *in vivo* an allergy is thus set up which results in destruction of the organism.

Summing up the changes briefly. In the controls there was leproma formation without any tendency to ulceration and the bacilli were generally smooth, short and granular. In those treated with promin alone lepromata were present,

but mostly retrogressing long bacilli predominating and "resistant" forms. Those treated with promin and carotenoid showed lepromata frankly retrogressed (in two they had gone altogether) and the bacilli were some long some with dark granules and apparently degenerated forms.

STANDEN O. D. Experimental Schistosomiasis. I. The Culture of the Snail Vectors *Planorbis boerri* and *Bulinus truncatus*. *Ann. Trop. Med. & Parasit.* 1949 Apr. v 43 No. 1 13-22. [13 refs.]

The successful establishment of aquaria for the growth and breeding of snail vectors of schistosomes in localities far removed from their native environment requires considerable care and attention to a variety of factors. In this paper the ecological requirements of the two important vectors, *P. boerri* and *B. truncatus* are described and discussed in relation to their culture in aquaria. Having outlined the habits of these two species including feeding and reproduction, the optimum conditions of temperature, light, aeration and pH of the aquaria are stated. The results of trials with various species of water plants showed that the most suitable forms are *Callitriche sp. alba*, *Eubryopsis palustris* and *Myriophyllum japonicum* which moreover are easily obtainable. The merits of other water plants are offset by certain undesirable characteristics.

For the maintenance of these snails under biologically balanced conditions a study was made of the rôle of protozoa and variety of aquatic invertbrates in the ecology of the snails. The harmful or beneficial actions of such forms as rotifers, oligochaet, crustacean and mollusc have been observed and are discussed. Of the crustaceans *Daphnia* plays an especially important part in controlling the numbers of unicellular organisms and the oligochaet act as useful scavengers of vegetable debris. The significance of the multiplication of other organisms as indicators of the general health of the aquarium is commented upon.

Detailed instructions are given as to the procedure to be followed in setting up a balanced aquarium for snail culture and for the successful maintenance together with useful hints as to the steps to be taken in the event of the appearance of signs of unbalance in the ecological environment.

ARIM M. A. & WATSON J. M. Comparative Efficiency of Different Methods of Packing the Snail Vectors of *Schistosoma haematodes* and *S. mansoni* for Transport by Air. *Ann. Trop. Med. & Parasit.* 1949 Apr. v 43 No. 1 39-40

Four well known methods of packing snails were tested in each case the snails were packed in wooden boxes 15 x 23 cm. with perforated lids. The

methods were (1) a layer of fine silver-sand, wetted to a paste, about 1 cm thick on the bottom of the box the snails were placed on this and a similar layer of wet sand placed on top of them, (2) as (1), with finely ground wood charcoal instead of sand, (3) open-ended tubes, 15 cm long and 2 cm in diameter, containing alternate layers of snails and wet dead leaves, the full tubes were covered with a double layer of fine-mesh gauze sealed in position with tape. The boxes containing the tubes were packed with more wet dead leaves, (4) a layer of wet pond-mud, about 1 cm. thick on the bottom of the box, with the snails on top of it and the rest of the space in the box filled with water-weed. This last is the method used for despatch abroad of snails from the Bilharzia Snail Destruction Section, Ministry of Public Health, Cairo.

The snails used were *Planorbis boissyi* and *Bulinus truncatus*.

All four boxes were placed in the shade for 72 hours (maximum daily shade temperature, 115°, 96° and 99°F).

After unpacking, the sand was very dry, the charcoal had caked, the leaves, mud and water-weed were quite moist.

The snails were removed under water, cleaned in running water at 27°C in a net and observed in aquaria for 24 hours. In the case of *P. boissyi*, the percentages of survivors in mud, sand, leaves and charcoal respectively were 97, 95, 94.5 and 90, corresponding figures for *B. truncatus* were 23.2, 2.0, 1.0, 11.0.

It is evident that packing in damp mud, in perforated wooden boxes with adequate air-space and covered with moist water plants was the most satisfactory. The results were borne out in the case of actual consignments sent abroad from Cairo (e.g. to Britain and to the U.S.A.).

Brief reference is made to other methods of packing for other species of snails.

DESA A. E. & MONTEIRO L. Urinary Schistosomiasis in India with a Report of One Case. *Indian J. Med. Sci.* 1949 June, v 3, No 6, 376-81, 2 figs on pl [16 refs].

Reference is also made to 9 previous cases in India.

ALVES, W. Miracil D in Urinary Bilharziasis. *South African Med. J.* 1949, May 28, v 23, No 22, 428-31.

BLAIR *et al* [this Bulletin, 1949, v 46, 556] have shown that urinary schistosomiasis can be cured by a 5-day course of miracil D totalling 75-100 mgm per kgm. In the present work, smaller doses were tried, *viz* —

(1) Sixty mgm per kgm given in six divided doses, twice daily for three days. Twenty young Africans were treated, nine complained of side effects such as nausea, headache or dizziness but there were no major disturbances. Four weeks later no living eggs were being passed in the urine and all twenty patients are considered cured.

(2) Sixty mgm per kgm given in four divided doses in four days to twenty young Africans. Only five complained of minor symptoms. Four weeks later, three of them were still passing occasional live eggs. Seventeen are considered cured.

(3) Seventy-five mgm per kgm in ten divided doses during five days, given to thirty-five young Africans. Nine had minor toxic effects. After four weeks all are apparently cured.

It is believed that patients who have not relapsed in four weeks are unlikely to relapse. "Miracil D appears to be a relatively non-toxic drug but it is extremely unpleasant to take and is definitely a gastro-intestinal irritant."

The subjects of these studies were schoolboys under discipline and patients in the Native Reserves might be less ready to take the treatment. Hot Mineral is strongly recommended for all cases where control can be exercised.

MOORE D. V., YOLLES, T. A. & MELENEY H. E. A Comparison of Common Laboratory Animals as Experimental Hosts for *Schistosoma mansoni*. *J Parasitology* 1949 Apr v 35 No. 2, 158-70 1 fig

"The common laboratory animals (mice, hamsters, rats, guinea pigs and rabbits) were infected with *S. mansoni* by two methods: intraperitoneal injection and cutaneous exposure. The course of the resulting infection was studied and the following points used as a basis for comparing the suitability of the animals as hosts for *S. mansoni*: percentage worm recovery; time required for the worms to reach maturity; and the presence of viable eggs in the feces.

1. *Mice*. Animals infected with 100 cercariae yielded an average of 1.4 per cent. worm recovery following intraperitoneal infection and 22.9 per cent. following percutaneous infection. Eight weeks after infection 80-89 per cent. of the worms were mature. Viable eggs appeared in the feces 8-8½ weeks after infection and egg passage continued until the death of the animals.

2. *Hamsters*. Animals infected with 160 cercariae yielded an average of 17.9 per cent. worm recovery after intraperitoneal infection, 18.1 per cent. after unshaved percutaneous infection, and 29.2 per cent. after shaved percutaneous infection. Eight weeks after infection 80-87 per cent. of the worms were mature. Viable eggs appeared in the stool 5-6 weeks after infection and egg passage continued until the death of the animals.

3. *Rats*. Animals infected with 100-6000 cercariae yielded an average of 0.9 per cent. worm recovery following intraperitoneal infection and 7.3 per cent. after percutaneous infection. Ten weeks after infection 67-80 per cent. of the worms were mature but were smaller than in mice and hamsters. Eggs were never demonstrated in the feces at any time.

4. *Guinea Pigs*. Animals infected with 500-1000 cercariae yielded an average of 0.5 per cent. worm recovery following intraperitoneal infection and 22.9 per cent. after shaved percutaneous infection. Eight weeks after infection 82 per cent. of the worms were mature but were smaller than in mice and hamsters. Eggs were never demonstrated in the feces at any time.

5. *Rabbits*. Animals infected with 500-15000 cercariae yielded an average of 0.3 per cent. worm recovery following intraperitoneal infection and 11.8 per cent. after percutaneous infection. Seven to 8 weeks after infection 63-67 per cent. of the worms were mature but were smaller than in mice and hamsters. Eggs were never demonstrated in the feces at any time.

6. It is concluded that mice and hamsters are the most suitable common laboratory animals for experimental infections with *S. mansoni*. Rat as unsatisfactory hosts because very few worms develop to maturity. Guinea pigs and rabbits are of value only for producing large numbers of worms and must be infected by percutaneous exposure.

WATSON J. M. & AZIM M. A. Comparative Efficiency of various Methods of Infecting Mice with *Schistosoma mansoni*. *J. L. P. Med. & Parasit.* 1949 Apr 43 No. 1 41-6

The authors exposed mice to infection with cercariae of *S. mansoni* by eight different methods with the object of establishing their relative efficiency. The technique employed in each method is described and it was concluded from the results that the partial-immersion method ranks first provided that precautions

are taken against contamination of the water by urine and faeces of the mice, which are lethal to the cercariae. The cover-slip method ranks next in reliability but has the disadvantage of taking up much time and only allows a limited application of cercariae. The tube method and oral method were also successful but less constant in results than the previous methods. Inoculation by vaseline ring, subcutaneous injection and intraperitoneal injection all gave relatively poor results. There was complete failure by the gastric-injection method.

J J C Buckley

HITCHCOCK, Dorothy J. **Penetration Characteristics of *Schistosoma mansoni* Cercariae** [Research Notes] *J Parasitology* 1949, Apr, v 35, No 2, 216-17

To estimate the time taken for the penetration of skin by a schistosome cercaria, the process was observed under a magnification of 40× and strong illumination, with the use of cercariae of *S. mansoni* applied to hamsters. The average time for penetration, measured from the time of placing the cercariae on the skin to the time of their disappearance below the surface, was 4.3 minutes for the 75 cercariae observed, the range being 2 to 15 minutes. With the use of mice instead of hamsters, the average time for 50 cercariae was 3.6 minutes, with a range of 2.5 to 8 minutes. When placed on the skin, in a drop of water, the cercariae usually swam around for one minute and then crawled by means of the oral sucker. During penetration they were attached to the skin by the oral sucker, the body being perpendicular. The tail was in violent movement but only broke from the body when the latter had completely penetrated. [From the description, it might reasonably be inferred that the cercariae penetrated the skin when fully submerged and without the aid of an evaporating film of water. (See also OLIVIER, this *Bulletin*, 1949, v 46, 849)]

J J C Buckley

MEIRA, J. A. & SOARES, J. C. M., Jr. **A biopsia retal no diagnóstico da esquistosomíase mansoni** [Diagnosis of *Schistosomiasis mansoni* by Rectal Biopsy] *Arquivos Facul de Hig e Saude Publica Univ de São Paulo* 1948, June, v 2, No 1, 45-90, 9 figs on 5 pls [24 refs] English summary

The authors, after referring to previous reports on the results of rectal biopsy examination in cases of *S. mansoni* infestation, record their own results in 42 cases in which 53 such biopsies were made. They refer in some detail to the findings of HERNANDEZ-MORALES & MALDONADO who, in 1946, reported on 138 patients 50 of whom had had no treatment, while 88 had been given antimonials. Of the former all were positive by rectal biopsy, although less than half [the authors state 41.6 per cent, presumably 21 of the 50, but why not 42 per cent?] were positive by faecal examination. Of the 88 who had had antimony treatment 70.3 per cent [62 patients] were positive by rectal biopsy, whereas faecal examination diagnosed only 16 (18.2 per cent). Moreover, for the untreated patients an average of 3.3 faecal examinations were needed before a positive finding was obtained and 10 were needed for those treated [see this *Bulletin*, 1947, v 44, 330]. The authors then detail the results in their own cases, in which rectal biopsy and faecal examination were both made, the one to check the other. Sometimes repeated faecal examination proved negative (in one case as many as 14) although biopsy was positive. All had been sent in as suspicious of *mansoni* infection. Seventeen were positive by biopsy and 25 were negative, and though among the former examination of faeces might be persistently negative, in none of the latter were faeces positive and biopsy

negative. [They state that biopsy specimens may be taken repeatedly without inconvenience or mishap but in one patient there was such profuse haemorrhage that blood-transfusion was called for and as regards the inconvenience the evidence of the patient might not coincide with that of the authors and should certainly have more weight.]

INGALLS J. W. JR., HUNTER, G. W., McMULLEN D. B. & BAUMAN P. M.
The Moluscan Intermediate Host and Schistosomiasis Japonica.
I. Observations on the Conditions governing the Hatching of the Eggs of
Schistosoma japonicum. *J. Parasitology* 1949 Apr., v 35 No. 2, 147-51

"The results from studies of environmental conditions which might be expected to influence the hatching of *S. japonicum* eggs indicated there is no effect on the rate of hatching as a result of the degree of intensity of illumination, agitation of fecal matter in the suspension, or osmotic stimuli. A diurnal or nocturnal cyclic frequency in hatching rates was observed. A temperature range of 23°C. to 30°C. was found satisfactory. The work indicated that to obtain consistently good results it is most important that the fecal material be thoroughly washed and the water in the hatching flask be clean and alkaline. The best miracidial yields were secured in water with pH 7-8. After hatching ceased in a flask, it was possible to obtain second and third yields by re-sedimenting the fecal material.

LEITCH, J. W. G. Continuous Sedimentation for the Concentration of Trematode Eggs in Faecal Suspensions. [Correspondence] *Nature* 1949 June 11 190, 1 fig

An apparatus for concentrating trematode eggs is described which has the advantage of rapidly reducing the faecal debris to less than half and of washing away colouring matter with the loss of only very few eggs. It is specially adapted for use with sheep faeces which have a high proportion of debris and it has proved of value in recovering eggs of *Fasciola hepatica* and *Lar. mystusomum* etc. It consists of a U-tube having a funnel at the end of one upright arm and a spherical flask 4.5 cm. (shown in list 4.5 mm.) in diameter at the other from which liquid can be siphoned off. The apparatus is filled with water except for an air lock in the spherical flask ("distillation splash head") and the faecal suspension having first been passed through a sieve (40-meshes per inch) is placed in the funnel. The siphon is then opened and the suspension passes through but eggs and heavier particles settle at the bottom of the U-tube from which they are recovered.

HARANT H. & MIDROUILLET Mme. Sur un nouveau cas de coenurus humain
[A New Human Case of Coenurus.] *Bull. Soc. Path. E. et* 1949 4
Vol. 56 173-4

The authors refer to the rarity of human infection by *Coenurus* and quote some of the few proved cases in the literature thus [Bulletin 1920 v 15 223 1932, v 29 54 and 416 1934 v 31 120 and 747 1941, v 39 631 and 872 also 1949 v 46 65 and 461].

They then give a brief account of a case in a peasant from the Department of Tarn. The patient was a deaf-mute and during a routine medical examination, a cyst about the size of a pigeon's egg was found in the left deltoid region. Operation showed that the cyst was partly embedded in the deltoid muscle and its wall was closely associated with the fibres. The cyst burst during surgical intervention, releasing a clear fluid. The cavity contained about 10 to 20 whitish granulations about the size of a pin's head. Microscopic examination revealed the presence of a coenurus which was identified as that of *Multiceps serialis*.
H J O'D Burke-Gaffney

COUTELEN, F, COCHET, G & BIGUET, J. Présence d'*Hymenolepis nana* dans le Nord de la France [*Hymenolepis nana* in the North of France] *Bull Soc Path. Exot* 1949, v 42, Nos 3/4, 106-11 [18 refs]

Six cases of *Hymenolepis nana* infection were recorded in the North of France in 1948 and all were autochthonous. Three were in a community of children, two were in one family and the sixth was an isolated case. Epidemiological investigation suggested a possible explanation of these infections.
H J O'D Burke-Gaffney

NEGHEM, R., FAIGUENBAUM, A., J., PILOTTI, A., M. & SILVA CAMPOS, R. Algunos aspectos epidemiológicos de la hidatidosis humana en Chile [Some Epidemiological Aspects of Human Hydatidosis in Chile] *Bol Oficina Sanitaria Panamericana* 1949, May, v 28, No 5, 469-77, 2 graphs

The English summary appended to the paper is as follows —

"From a study made of some of the epidemiological aspects of hydatidosis in Chile during a period of 12 years (1933-1945), the authors arrived at the following conclusions: the incidence of hydatidosis in Chile is low in relation to other common infections, though it must be said that during recent years the epidemiological curve has gone up; as to its geographical distribution, in varying degrees of intensity, it has spread throughout the country, although the disease has no special preference as regards sex, it occurs slightly more frequently in men; it is unknown in nursing children; the incidence is low in children under 10 years and in persons over 60 years old, and 90 per cent of the cases are found in persons from 11 to 59 years of age; the over-all death rate for this disease in Chile remains stationary although the death rate for the total number of persons affected with the disease has risen during recent years."

JOYEUX, C & BAER, J. G. L'hôte normal de *Raillietina* (R) *demerariensis* (Daniels, 1895) en Guyane hollandaise [The Normal Host of *Raillietina* (R.) *demerariensis* in Netherlands Guiana.] *Acta Tropica* Basle 1949, v 6, No 2, 141-4

Two cestode strobilae which had been collected from a howler monkey, *Alouatta seneculus*, in Surinam, were identified as *Raillietina* (R) *demerariensis*, a species which has hitherto been recorded only from man. The material is described in detail and the chief morphological characters of this species and of *R. alouattae* Baylis, 1947, which it closely resembles, are tabulated.

R. alouattae also occurs in the howler monkey, *Alouatta macconnelli*. The howler monkey is thus established as the normal host of two species of *Raillietina*, one of which is capable of infecting human beings.

J J C Buckley

BARR, J. G. KOURI P. & SOTOLONGO F. Anatomie position systématique et épidémiologie de *Iuermicapsifer cubensis* (Kouri, 1938) Kouri 1940 cestode parasite de l'homme à Cuba. [Anatomy Systematic Position and Epidemiology of *Iuermicapsifer cubensis* (Kouri, 1938) Kouri 1940, Cestode Parasite of Man in Cuba. *Acta Tropica* Basle 1949 v 6 No. 2, 121-30, 14 figs. [15 refs.]

"A detailed anatomical study of *Iuermicapsifer cubensis* based on the original material deposited in the School of Tropical Medicine in Havana shows that we are dealing with a single well defined species of this genus.

"Over one hundred cases have been recorded so far from the western part of the island. It is very likely however that this parasite will be found in other parts of Cuba as well as in Porto-Rico and Venezuela.

Children of the age 1-5 years and 9-11 years are most frequently infested. All cases except two have been recorded from white children.

"It is probable that parasitism is accidental and that the normal host will be found amongst the Cuban fauna. No systematic research has been made so far with this end in view. Among native rodents, *Julis* (*Capromytilorides* and *C. percherillus*) apparently do not harbour this worm.

Iuermicapsifer is discovered by finding the ripe segments, singly in the faeces. These cannot, however be distinguished from those of *Railletius* the presence of which in the West Indies, is quite possible. It is always necessary to recover the scolex and to examine it for the presence of the peculiar hooks of this genus.

RAYLIS, H. A. A New Human Cestode Infection in Kenya. *Iuermicapsifer arricanthus* sp. n. Parasite of Rats. *Trans. Roy Soc Trop Med & Hyg* 1949 May v 42, No. 3 531-4, 5 figs. [22 refs.]

Two strobilae of *Iuermicapsifer arricanthus* (Hofend, 1917) were evacuated, after anthelmintic treatment by a boy aged two from Kenya who had been passing tapeworm segments. The boy had lived in Nairobi until April 1948 when he came to England and some weeks later was admitted to hospital. The verminicide employed was filix mas, miliums 15 given with jam and honey in the evening and retained during the night. Early next morning syrup of figs, drachm 1 was given and the tapeworms were recovered in the stool.

In the fresh condition these measured about 2.5 cm. and after preservation were about 17.9 cm. and 18.5 cm. respectively with a maximum width of 3 mm. The segments numbered about 315 and 390 and, except for the terminal segments, were broader than long. As the species is new to medical literature the author gives a detailed and complete description of it based on this human material and a specimen from a rodent host. A hitherto unmentioned feature was noted in the excretory system, in which the ventral longitudinal vessels were seen to be 4 to 6 in number and to be interconnected by a network of transverse vessels.

This species has been recorded from rodent hosts in various parts of Africa. In the Sudan from *Arvicola niloticus kordofanensis* in Dahomey from *Arvicola niloticus rufinus* and *Oryzomys hypomelanus* in Nigeria from *Hylomys reticulatus* Lem. seems *stratus* (under *krump*) and *Rattus* (*Mastomys*) *crucis cristaticeps* in French Guinea from *Ptilomys* (Gould) *campanus* in Tanganyika, from *Rattus* (*M. ulmanni*) *concha micromelanus* and *Heliophobus argenteocinctus* *emini* in the Belgian Congo from *Rattus* (*Mastomys*) *concha* (subsp. n.) in Southern Rhodesia from *Mastomys natalensis* in S. Africa, from *Thalomys* (*M.*) *mergeri* and *Oryzomys* *moysi* (Alcock)

I. arvicanthidis has yet to be recorded from rodents in Kenya, it is considered that its present occurrence in a human host represents an occasional or accidental infection

With the interesting exception of *I. cubensis* (Kouri, 1938) recorded from human beings in Cuba [see this *Bulletin*, 1941, v 38, 113] *Inermicapsifer* appears to be an African genus and the suggestion is made that the Cuban species may have been introduced from West Africa. Moreover, the possibility exists that *I. cubensis* and *I. arvicanthidis* may be identical, as the author's comparison of the two species seems to indicate

The life-cycle of *Inermicapsifer* is unknown, but in other members of the Anoplocephalidae, in which this genus is placed, the intermediate hosts have been found to be mites. However, it is suggested that the vector of *Inermicapsifer* is more likely to be an insect, as its egg capsules appear too large to be swallowed by mites. The close resemblance of the egg capsules to those of *Railhetina*, of the family Davaineidae, certain species of which are transmitted by beetles and ants, supports the idea of an insect intermediary for *Inermicapsifer*, and if this should be confirmed by future researches, it would further establish the resemblance between the two genera and lead to a reconsideration of the present classification of *Inermicapsifer*

A general discussion and review

BEAVER, P C Quantitative Hookworm Diagnosis by Direct Smear
J Parasitology 1949, Apr, v 35, No 2, 125-35, 3 figs [11 refs]

The use of direct faecal smears in egg-counting for an approximate estimation of hookworm burden, is dependent on the assumption that the eggs are uniformly distributed in the faecal mass, and its value is impaired by the fact that faecal smears vary in volume and do not represent a uniform sample of faeces. The author devised a method of standardizing faecal smears and then applied it to determining the reliability of egg-counts of standard smears as compared with the Stoll dilution egg-count method.

To standardize direct smears, they are brought to a uniform standard density by means of a photo-electric foot-candle meter. A drop of water is placed on a slide and a small portion of faeces is mixed into it until an even density is obtained. It is then spread to a diameter of 16 mm and the slide is placed on the meter over an aperture of 16 mm diameter. Vertically above there is an electric lamp (75-100 watts) adjusted to give a reading of about 20 foot candles when a clean slide is placed over the aperture. Faeces are then added to the smear until the light is reduced to exactly 10 foot-candles. All forms of gross debris are removed from the smear before it is made up to the standard density. The eggs are then counted in the smear after it is covered with a coverglass.

Counts were carried out on stools from 10 different persons by this method (standard direct smear) and by a dilution method. Ten successive counts were made on each stool by each method. In another series five successive counts were made on 41 stools. Comparison of the two methods showed that they are about equally variable, the average of the coefficients of variation being 21 and 20 respectively in the first series and 22 and 25 in the second. The relationship between the number of eggs per slide and the number of eggs per cc of stool was also examined and a close correlation was found between the two methods. With the use of a conversion factor of 300, standard direct smear counts can be

interpreted approximately in terms of number of eggs per cc. on a formed-stool basis. Periodic egg-counts on stools from the same person gave results as uniform by standard direct smear as by dilution methods.

Investigation of the relationship between egg-counts and hookworm burden was carried out by egg-counts made by both methods followed by worm counts after treatment with tetrachlorethylene. From the results obtained it was concluded tentatively that each egg by standard smear count represents roughly 10 mature worms.

CRUZ J. R., GUTTINGCO A. & KASILAG, Wilhelmina R. Observations on Hookworm Anaemia in the North General Hospital. *J. Philippine Med. Ass.* 1949 Apr. v. 25 No. 4 191-4

Hookworm anaemia has become much more prevalent than before in Manila during the last year 1947-1949. The authors attribute this to the Japanese occupation, but note that the widespread increase in hookworm infection took several years to produce an increase in cases of hookworm anaemia. Another factor is the present-day relative rarity of anaemia due to malaria and malnutrition.

The anaemia was usually of the hypochromic microcytic type but in 6 cases it was hypochromic macrocytic and in three hypoplastic or aplastic. Of 10 patients with aplastic anaemia died there was one other death in the series.

About 60 per cent. of 47 cases in this series were diagnosed at the first stool examination and about 14 per cent. required 3 to 7 examinations before ova were found.

Most of the patients required 2 or 3 courses and 3 required 4 courses of either heylresoreinol crystals 1.0 to 1.4 grammes, or tetrachlorethylene 3 ml. at intervals of 8 days. Despite these repeated courses 15 of the 47 patients were discharged with ova in the stools.

BRAY BLANQUET M. A propos de l'activité de l'essence de *Chenopodium ambrosioides*. (On the Activity of the Oil of *Chenopodium ambrosioides*.) *Bull. Soc. P. M. Exot.* 1949 v. 42, Nos. 3 & 4 116-18.

The French preparation, oil of *Chenopodium ambrosioides* locally grown in Montpellier which has anascaridol content of 60 to 80 per cent. was given to several patients with nematode infections in the doses usually prescribed for the American preparation, namely 1.0 to 1.5 ml. for an adult divided into three doses, given in the morning on an empty stomach. Intervals of an hour followed one and a half hours after the last dose by 30 to 40 grammes of sodium sulphate. For ankylostomes this is often repeated several times at intervals of not less than 10 days.

This dosage was given to 30 patients and was well tolerated except in one cardiac case. In one case of *Trichocephalus* infection there was a clinical and parasitological cure and in another a reduction in the number of eggs in the faeces.

Nine patients with ankylostomiasis were treated. Sometimes as many as 100 adult worms were passed within 48 hours. In all there was improvement in the symptoms and sometimes in the blood picture. In seven cases there was a clinical and parasitological cure the latter being confirmed by at least two stool examinations.

The best results were obtained with *Ascari* infections. Nineteen patients were given a single treatment of 1.0 to 1.5 ml. all were completely freed of the parasites the results being controlled by at least two stool examinations.

The author concludes that the French oil of chenopodium is as effective as that imported from the United States before the war and now unobtainable in France [This is the therapeutic trial with the locally manufactured oil referred to in this *Bulletin*, 1947, v 44, 1013 (HARANT, *et al*)] L E Napier

BRANNON, Mary J C & FAUST, E C Preparation and Testing of a Specific Antigen for Diagnosis of Human Strongyloidiasis *Amer J Trop Med* 1949, Mar, v 29, No 2, 229-39

"A test antigen prepared from clean filariform larvae of *Strongyloides* cultured from the feces of the chimpanzee and extracted in isotonic (0.425 per cent) salt solution or Coca's solution, in dilution 1:100 produced 23 positive intradermal reactions and 25 positive precipitin tests in 25 chronic cases of human strongyloidiasis. Additionally there were two doubtful intradermal reactions, one in a moribund patient and one in a patient who had very severe exfoliative dermatitis. The precipitin titers ranged from 1:5,000 to 1:30,000. This antigen produced consistently negative, doubtful or weak intradermal and precipitin tests in 105 of 108 presumably uninfected control cases.

"The diagnostic significance of the positive intradermal and precipitin reactions has been demonstrated in these cases of *Strongyloides* infection. The tests provide a reliable index of infection. In cases of presumably cured *Strongyloides* infection the value of the intradermal and precipitin test is not so clear. It is not known how long after cure the intradermal reaction will remain positive, although it is likely that the precipitin test as carried out indicates the presence of specific antibodies."

LIE KIAN JOE Helminthiasis of the Intestinal Wall caused by *Oesophagostomum apistomum* (Willach, 1891) Railliet and Henry, 1905 *Documenta Neerlandica et Indonesica de Morbis Tropicis* Amsterdam 1949, Mar, v 1, No 1, 75-80, 3 figs [12 refs]

Eight nodules were found at autopsy in the submucosa of the caecum and ascending colon of an Indonesian male, aged 45 years. The nodules were 7 mm to 10 mm in diameter, semi-globular in shape and inconspicuous, and when they were opened a living nematode was found in each of six of the nodules. Two nodules which were perforated were empty, but a dead female worm was found in the lumen of the intestine. Of the 7 worms, 4 were males and 3 were females. Histologically the nodules showed a wide cavity deep in the mucosa, surrounded by necrotic material and a thin layer of connective tissue, containing lymphocytes, plasma cells, other round cells and a few neutrophilic leucocytes. The necrotic layer tends to liquefy and it is assumed that the worm produces substances that dissolve the cyst wall.

The worms are identified as *Oesophagostomum apistomum* and a detailed description of their morphology is given and illustrated J J C Buckley

OCHSNER, A, DEBAKEY, E. G & DIXON, J L Complications of Ascariasis requiring Surgical Treatment. Report of Case with Abdominothoracic Complications *Amer J Dis Children* 1949, Mar, v 77, No 3, 389-407, 10 figs [Refs in footnotes]

Complications of ascariasis requiring surgical intervention have been frequently recorded in the literature. Since they are usually of a serious nature and offer a rather poor prognosis, it is imperative that the diagnosis be made early and treatment be promptly instituted. The types of lesion produced include mechanical obstruction produced by the adult worms and bacterial

contamination transmitted by its migratory habits. Since ascariasis is common in children a higher incidence of surgical complications would be expected in them but they are not infrequently encountered in adults. Ascarides may produce mechanical obstruction in any hollow organ such as the trachea, intestine, bile or pancreatic ducts and others. Intestinal obstruction from a bolus of entangled worms most commonly occurs in the lower ileum. Intussusception and volvulus may result from the irritation caused by the presence of one or more worms which do not necessarily obliterate the intestinal lumen. Ulceration and perforation of the small or large intestine may occur with migration of the worms into the peritoneal cavity. It is not uncommon to find ascarides in a suppurating or gangrenous appendix of 1 000 surgically removed appendices in a New Orleans hospital ova of *A. lumbricoides* were found in the faecal contents of 48. Migration of the parasite into the bile or pancreatic ducts leading to suppurative or haemorrhagic pancreatitis, has been frequently reported. Multiple hepatic abscesses, which may rupture into the peritoneal cavity or thorax are occasionally met with. The migrating larvae may cause bronchopneumonia, as was demonstrated by the Japanese brothers Koiso in 1922 (this Bulletin 1923 v. 20, 235) by experiments on themselves, and larvae and ova have been recovered from the sputum in cases of pulmonary infection which may proceed to empyema and abscess formation.

Diagnosis depends on recovering the ova from the stools or larvae or worms from the involved organ. A history of vomiting or passing worms is important and blood examination usually reveals anaemia and eosinophilia. An X-ray examination after a barium meal may show shadows due to the ingestion of barium sulphate by the ascarides. A rule however the diagnosis is rarely made before operation. The authors prefer hexylresorcinol as the anthelmintic before operation but warn against too vigorous employment of purgatives which may produce intestinal obstruction. At operation enterotomy and evacuation of the bolus is the only safe method but the length of bowel involved may be so great that this is not practicable. In such cases a temporary ileostomy may be performed. Intussusception and volvulus as best corrected without enterotomy though gangrene may necessitate resection. The treatment of perforation, general peritonitis or local abscess is on the usual surgical lines. Invasion of the gall bladder calls for cholecystectomy and in all such cases the common bile duct should be explored and drained. Hepatic abscesses are usually multiple and are treated by evacuation of the worms and drainage after packing off neighbouring organs.

The authors conclude with an account of a case of multiple hepatic abscesses in a child aged 20 months in whom after the evacuation of an abscess in the right lobe of the liver which contained 4 worms a similar mass was discovered high up on the dome of the right lobe too inaccessible to be dealt with at the time. This subsequently perforated the diaphragm and infected the thorax and the patient did not survive thoracotomy. At autopsy no worms were found in the cavity in the liver nor any in the intestinal tract.

A large number of references are summarized in this paper and there are several good illustrations.

(A review of this subject by H. MILWINSKY was summarized in this Bulletin 1946, v. 43, 508.) H. L. Harcourt

Wootman H. M. *Flaria* in the Anglo-Egyptian Sudan. *Trop. Med. & Hyg.* 1949 May 4, v. 6, 543-58. 1 map, 10 text figs. 5 refs.

Except for a small focus of *Haemeria lauranti* in the Nuba Mountains, filariasis is confined to the two southernmost provinces (the Sudan Equatoria

and Bahr el Ghazal Microfilariae only of *W bancrofti* have been found infrequently, no clinical cases have been diagnosed there recently

Loa loa infection is found from 6°N down well into the Belgian Congo and from French Equatorial Africa to 30°E. About 20 per cent of the native population are affected. " Its only proved vector is *Chrysops distinctipennis* and *C longicornis*, which occur in the ratio 26 : 1 " Its development in these species is much slower than that described by CONNALL and CONNALL [this *Bulletin*, 1922, v 19, 654] for *C silacea* and *C dimidiata*. Of 600 wild flies dissected, 0.6 per cent showed embryos of *L. loa* [sic ? 3 or 4 flies]. The author considers that these are probably not the main vectors in the Sudan. Other vectors are considered. In a species of *Haematopota* fed on an infected man some development occurred.

Acanthocheilonema perstans is found in 50 per cent of the native population in these southern provinces of the Sudan. *Culicoides grahami* is presumably the vector.

The hyperendemic area for *Onchocerca volvulus* lies between French Equatorial Africa and 30°E, and between 6°N and 9°N. South of this area occasional nodules due to this parasite are seen, but blindness is rare. Two surveys were made at points on the Sue river, at approximately latitudes 5°N and 6°N, in the former 50 per cent of persons selected (with nodules or other suggestive signs) showed microfilariae in their skins and in the latter 88 per cent. In the latter area 77 per cent of the apparently healthy population showed microfilariae, of 1,440 people in all, the percentage with nodules was 3.1 and with blindness was 0.48. The blindness did not all appear to be due to *O. volvulus*.

Antigen made from avian filariae was used for intradermal tests. 91.7 per cent of cases gave a positive result and 5 a weak positive [the nature of the cases is not stated].

WANSON, M. Essai de traitement curatif de la filariose à *Loa-loa* et de la filariose apériodique par les dérivés de la pipérazine [Therapeutic Trial of Piperazine Derivatives in Loiasis and Aperiodic Filariasis.] *Ann Soc Belge de Méd Trop* 1949, Mar 31, v 29, No 1, 73-80.

In his main series the author treated 10 Europeans and 36 Africans with hetrazan. In some subjects (not included in his main series) who did not take the full course of hetrazan, it was found that doses of 0.5-1.25 mgm per kgm three times daily for 10-21 days were ineffective and the number of microfilariae was unchanged.

In the cases of infection with *Loa* alone, the Europeans showed the usual symptoms, especially eosinophilia and prurigo. The 15 African patients were mostly without symptoms but in 4 of them (in whom the blood contained 500-800 microfilariae per 20 mm³) there was emaciation. Twenty-one of the African patients harboured both *Loa* and *A. perstans*.

The dosage was 2 mgm of base per kgm thrice daily for 10 days by mouth. This was well tolerated, even by the 4 heavily infected Africans. *Mf loa* disappeared rapidly from the blood within 48 hours.

Many of the Europeans complained of subcutaneous sensations resembling those caused by movements of the worms. There was also a transitory recrudescence of prurigo and other symptoms. After 48 hours, these symptoms gradually disappeared the prurigo being the last to go. In 5 out of 10 cases, the apparent cure has lasted 3 months. But usually in both races the symptoms return after 4-12 weeks and the patients request further treatment. Accordingly the author recommends courses of 15 or 21 days, repeated 2 to 5 times at intervals of one month. Such courses have led to great and prolonged clinical

improvement but it is premature to claim radical cure. Hetrazan is not effective against *Ancyrostrongylus*, *Trichostrongylus* or *A. colodinus* [but see this Bulletin 1949 v 46 835 where OLIVER-GONZALEZ *et al* claim that all worms [45.0m] were apparently removed from 3 of 6 patients after hetrazan]. Doses of 450 mgm. per day for 15 days have had no effect on 4 persons. F Hawk

LAGRANGE E. Essais de traitement des filarioses à *Loa-loa* et *O. colodinus* par le diéthylcarbamazine Cl₂. [Treatment of Filariasis due to *Loa-loa* and *O. colodinus* by Diethylcarbamazine Chloride.] *Ann Soc Belge de Méd Trop* 1949 Mar 31 v 29 No 1 19-22.

The author describes 3 cases of loiasis and 2 of onchocerciasis treated with Hetrazan i.e. diethylcarbamazine (this Bulletin 1948, v 45 532 1949 v 46 275 565).

Case 1—Male—47 years. Eighty-one kgm. with Calabar swellings for more than 18 months. No microfilariae in blood. He took 0.3-0.4 gm. Hetrazan three times daily for a total of 3 gm. Has remained free from symptoms 8 months.

Case 2—Male—60 years. Eighty kgm. Calabar swellings for more than 15 months. Microfilariae present in blood. The first two doses of 0.4 gm. Hetrazan caused pyrexia (38-2°C.) and rigors. Total dosage 3 gm. Four months later he had a relapse (Calabar swelling) which was not treated.

The third case was similar.

The other two cases are said to have been "*gale filariens*" although microfilariae were never demonstrable. When Hetrazan was given the usual allergic reaction was delayed or absent so the diagnosis remains doubtful. The patients seem to have improved after treatment. When Hetrazan is given to cotton rats infected with *Leishmanoides carini* it does not kill the adult worms. F Hocking

WATSON M. L. Hetrazan dans la période d'invasion de l'onchocercose (Hetrazan during the period of invasion of Onchocerciasis.) *Ann Soc Belge de Méd Trop* 1949 Mar 31 v 29 No 1 83-9

Hetrazan is effective in destroying the microfilariae of *Onchocerca* in the skin but it is less effective against the adult worms which completely resist the course of 21 days. Three months after such a course excision of nodules shows living and apparently normal adult males and females. The present paper refers particularly to a patient treated during the incubation period. A European aged 43 years was bitten on September 7th, 1948 by three *S. m. damnosum* which were afterwards dissected. One contained five infective larvae. Forty-eight hours later the calf of the patient's leg was oedematous, whit and itching for 2½ cm. around an insect bite. The patient had previously been exposed to *S. m. m.* bites but he had not previously responded in this fashion. On October 1st the swelling had spread round the ankle and was different from the usual reaction to *S. m. m.* bites. By October 15th, the skin resembled "*peau d'orange*" and was finely papular. During all November the patient suffered from lassitude and insomnia. On December 2nd, examination showed pachydermia of the lower part of the leg and of the dorsum of the foot with three hyperpigmented plaques. No microfilariae could be found but there was an eosinophilia of 14 per cent.

On December 3rd & 5th, there was a general urticarial reaction over the trunk and extremities, this was relieved by antihistamine treatment. By December 25th the local symptoms in the leg were worse and the patient had lost 3 kgm. in weight. Treatment was started with Hetrazan which immediately

caused exacerbation of the pruritus and local symptoms, controlled by Histaphen. The dosage of Hetrazan was 150 mgm three times daily for 17 days.

On December 31st, there was definite clinical improvement of all symptoms but there was intense lassitude.

On January 9th, the skin had become thin and supple again, and by February 28th the patient was completely cured.

This history is interpreted as being a developing infection of *Onchocerca* which was cut short by Hetrazan. [An interesting and instructive case, the original paper should be consulted for the full details] F Hawking

KERSHAW, W E Observations on *Litomosoides carini* (Travassos, 1919) Chandler, 1931 II The Migration of the First-Stage Larva *Ann Trop Med & Parasit* 1949, Apr, v 43, No 1, 96-115, 6 figs [29 refs]

"1 A series of experiments are described in which a direct, as distinct from an indirect, attempt was made to define the time taken by the first-stage larva of *Litomosoides carini* to migrate, immediately after birth, from the adult female, through the pleural space, to the peripheral circulation. With uninfected cotton rats as recipient hosts, adult female worms were transplanted to the pleural cavities, pleural exudate containing developing larvae was injected into the pleural cavities, and blood containing fully developed larvae was injected intravenously into the pleural and peritoneal cavities and into the subcutaneous tissues.

"2 The migration-time from each of these sites, though variable, was found to be commonly one day, though in one experiment larvae were found in the peripheral circulation one hour after the surgical transfer of worms. The variability in the results was too great for differences in the migration-rates of larvae in different stages of development to be defined, nor was the age of an infection found to affect the results.

"3 The persistence of the larvae in the peripheral circulation was found to vary from days to weeks or even months.

"4 These results are compared with observations on other filariae, and the necessity is stressed of observing host-parasite specificity and of using large numbers of larvae in such experiments, in order to allow for uneven distribution in the recipient host.

"5 The rapid and urgent development of the larva of *L. carini* to attain a form infective to the next host, and its persistence in the site where an optimum opportunity of transfer is presented, are compared with the corresponding developmental stages of other nematodes parasitic in man, animals and plants, and are found to be not inconsistent with them."

LAGRANGE, E Essais de chimiothérapie sur la filaire (*Icosiella neglecta*) de la grenouille (*Rana esculenta*) [Chemotherapeutic Studies on the Filaria (*Icosiella neglecta*) of the Frog (*Rana esculenta*)] *Ann Parasit Humaine et Comparée* 1949, v 24, Nos 1/2, 49-53, 1 fig & 1 pl

Frogs (*Rana esculenta*) collected at two places in France had an infestation rate of 15-35 per cent with *Icosiella neglecta*. Other frogs were obtained from Léopoldville and microfilariae (and a few adults) were found in *R. galamensis* and *R. occipitalis*. Antifilarial activity has been found in two of a series of compounds tested.

(1) Methyl violet This kills the microfilariae of *Dirofilaria repens* at 1-400 000 in 17 hours. When given intravenously to frogs it seems to have some action in killing or sterilizing the adult female worms although the microfilariae are unaffected. Unfortunately this compound proves toxic in the rat and the dog and high doses cause pulmonary oedema.

(7) Diphenylacetic U.C.R. (hydrochloride of oxyamino-phenyl-dichlorarsine or oxophenarsine). When this was given to a patient infected with *Loa* it caused transient improvement of his symptoms. When injected into frogs it caused death of most of the adult female worms although the microfilariae were more resistant. Many organic arsenical compounds show marked filaricidal powers against the adult worms of *Loa* in cotton rats.) F. Harsh.

SCHIFFNER W. & SWELLENGREBEL, N. H. Retrofection in Oxyuriasis. A Newly Discovered Mode of Infection with *Enterobius vermicularis*. *J. Paediatrics* 1940 Apr. 1, 35 No. 2, 133-48 6 figs.

Hitherto oral ingestion of the eggs of *Enterobius vermicularis* has been thought to be the only method of acquiring this parasite. During an investigation lasting for five years the authors discovered that another method exists wherein the larvae having hatched from eggs deposited in the perianal region re-enter the body via the anus and migrate upward to the caecum where they grow to maturity. For this unique helminthological phenomenon the new word "retrofection" is coined. Thus, to the existing knowledge concerning the well-lubricated machinery of dissemination and transmission which characterizes the life-cycle of what might justly be termed man's most personal parasite there is now added a further refinement of procedure whose implications have yet to be fully explored. The biological curiosity attaching to the life-cycle of *E. vermicularis* as exemplified by the external migration and death of the gravid females and the rapid incubation of the eggs is much enhanced by this finding which not only reveals an unparalleled phase in the known man-helminth relationships but opens up a new line of study in the wide range of hosts which harbour oxyurid worms. From the medical aspect it will explain much that has been perplexing about the refractory nature of pin-worm infections and it indicates at least one new approach in prophylaxis. Of importance too is the effect it should have in reducing if not obliterating the stigma of uncleanness which sometimes is unhappily associated with pin-worm infection in adults.

Before proceeding with the main theme of the paper the authors demonstrate by means of graphs showing the results of daily anal egg recoveries on infected persons over long periods of time that in the case of oral ingestion of eggs different pictures of the infection are produced by different modes of egg transmission. Three modes are discussed: 1. Direct transmission by fingers. 2. Indirect transmission or secondary contamination: food and fingers. 3. Dust-borne transmission.

1. Direct transmission from the anal region to the mouth: common in children rare in adults and produces a picture of chronic heavy infection, which is terminated at least temporarily by treatment.

2. This method involves both children and adults. In adults there is spontaneous self-cure in the absence of re-infection but in children self-cure is prevented by continuation of finger transmission. Less intense infections result from this method.

3. Dust-borne transmission: common in school where the environment is favourable and results in chronic but light infections which appear intermittently throughout the year. It is largely responsible for the widespread distribution of pin-worms.

Proof of the existence of the hitherto unknown retrofection was obtained experimentally and it was observed to have occurred naturally in circumstances which allowed no other possible interpretation. The idea had its inception in

the known fact that larvae have occasionally been found crawling on the anal region, having hatched out "precociously" and presumably to no purpose. In the experimental work, eggs were hatched out in artificial gastric juice and the larvae were applied to the sphincter portion of the anus in two human volunteers. One of these was treated thus with about 100 larvae and the other (the senior author of the paper) with about 150 larvae. Both subjects became infected after pre-patent periods of 76 and 43 days respectively. A third volunteer, aged 22 years, who had been proved negative for oxyuriasis for about 5 months previously, was inoculated perianally with 50 larvae and became positive after an incubation period of 76 days. Two of these subjects subsequently provided natural evidence of retrofection when, after a period of freedom from infection, they again became positive. Re-examination of previous data also confirmed the existence of retrofection.

It is remarked that retrofection probably occurs in children but is difficult to prove as it is likely to be masked by the occurrence of oral transmission. In adults, however, although as shown by the Amsterdam experiment it does not invariably occur, it should be suspected in all cases of chronic oxyuriasis. It would present a picture of recurrent infection at periods not exceeding the life-span of the worms, i.e. 37 to 93 days, since one generation must follow another in succession. "It will now be the task of the family physician to investigate to what extent retrofection is common in adults. Once recognized, termination of the infection can be achieved without drug therapy. Since it is known that these infections can end spontaneously, mechanical prophylaxis must be employed to achieve the goal of interrupting the chain of recidives. This is done by removing, for a certain period of days, the eggs from the anal region before the larvae have a chance to hatch, that is, every 6 hours, the time required for the enclosed embryos to mature in air."

HANEL L & WEISS, R. Beitrag zur Wurmithherapie [Contribution on the Treatment of Helminthiasis] *Deut med Woch* 1949, June 10, v 74, No 23, 745-6

The author refers to previous correspondence on the treatment of enterobiasis and tells of the success he has had with phenothiazine, known also under the names dibenzothiazine and thiodiphenylamine, commercially as Contaverm, the dose being one tablet thrice daily for a child, two for the adult. It is insoluble in water or dilute acid or alkali. When oxidized it becomes more soluble, is absorbed and excreted in the urine which it colours a reddish brown. It does not cause untoward symptoms such as nausea and vomiting as may crystal or gentian violet. Some have reported it as causing anaemia [this *Bulletin*, 1946, v 43, 940] but that, in the authors' opinion, was due to excessive dosage. They gave 7 gm in 4 days, whereas the present authors advise doses up to 6 gm spread over 5 days, for a patient weighing 60 kgm and dosage according to weight, not age. For children he gives 7 to 15 tablets of 'Contaverm', i.e. 1.4 to 3 gm of phenothiazine, spread over 5 days. Details are given of two patients, a boy of 5 who had had the infection for two years, and a woman of 37 years. Both had had intractable pruritus and resultant eczema. These distressing symptoms cleared up in 4-5 days and the worms a day or two later, the dose being one tablet thrice daily for the child, two for the adult. Although the symptoms cleared up the course was repeated after an interval of three weeks, the child being given half the former dose. During observation for several months there had been no signs of any recurrence.

H Harold Scott

lesions were confined almost entirely to the Purkinje cells, which showed acute hyaline necrosis.

These findings accord with clinical experience in human cardiac beriberi. Initial biochemical changes causing disturbance of the conducting mechanism are reversible but may develop into irreversible morphological lesions.

AUFFRET C. & TANGUY F. *Considérations sur 139 dosages de vitamine C dans le sang de militaires africains de différentes unités de Dakar*. [Notes on 139 Estimations of Blood-Vitamin C Levels in African Soldiers.] *Bull. Méd. de l'Afrique Occidentale Française* 1948 v 5 No. 1 77-80.

Of 99 soldiers of different races and varied length of service at Dakar 77 had blood ascorbic acid levels of less than 4 mgm. per litre. All but three of a group of 40 recruits from Dahomey showed similarly low levels and in none did the level exceed 7 mgm. per litre. These levels indicate definite depletion. Bleeding gums were found in some subject of the latter group but frank scurvy was rare.

The authors discuss the relationships of vitamins C and 1 to each other and to the causation of the haemorrhagic manifestations associated with scurvy and pre-scurvitic states. [They quote numerous authorities but give no references.]

Dean A. Smith

AUFFRET C. & TANGUY F. *Vitamine C dans les organes d'enfants et d'adultes africains de la région dakaraise*. [The Vitamin C Content of the Organs of African Children and Adults in the Dakar Area of French West Africa.] *Bull. Méd. de l'Afrique Occidentale Française* 1948 v 5 No. 1 167-72.

Estimations of vitamin C were carried out on the liver, spleen, pancreas, kidneys, heart and suprarenals of 27 persons who had died of apparently non-nutritional causes. The results were compared with those found in three tuberculous subjects whose ascorbic acid excretion measured shortly before death had indicated saturation.

The average levels in the nutritionally normal subjects were much lower of the order of half than those in the saturated subjects.

Although none of the persons showed any clinical evidence of deficiency the authors consider that their functional efficiency and capacity for work must have been greatly impaired. A plea is made for extended dietary use of the many good fruit and vegetable sources of vitamin C available locally especially the fruit *Dalmanella senegalensis*.

SPRUE

SAINT-ETIENNE J. *La sprue tropicale*. [Consideration pathologique.] *Observations on the Pathological Features of Tropical Sprue*. *Méd. Trop.* Marcellin. 1949 Nov-Dec v 8 No 5 571-86. Numerous refs.

This article is a résumé of the various investigations conducted mainly by Anglo-American workers during the recent war. This renders it almost impossible to write a summary of the numerous investigations which have been adequately reviewed in this *Bulletin*.

There are several misprints especially with reference to the spelling of English names.

L. Manson-Bell

WOODRUFF, A. W. Aetiological and Prognostic Features in Tropical Sprue. A Study of 47 Cases over a 2½-3 Year Period. *Trans Roy Soc Trop Med & Hyg* 1949, May, v 42 No 6, 605-12, 1 fig [12 refs]

The subjects of the paper are 47 patients with tropical sprue admitted to an R A I mobile field hospital serving members of the Air Force in the Chittagong area, from July 1944 to June 1945. "There was a tendency for the cases to occur in small groups among personnel of individual units."

A figure shows that the rise and fall of the monthly incidence curve of the 47 cases of sprue (month of onset of symptoms) almost coincides with, but actually slightly precedes, the incidence curve of 72 cases of amoebic dysentery. The peaks fall in July and the trough of the sprue curve from November to March.

The duration of service in India before onset was 6 to 12 months in 27 per cent, 12 to 18 months in 16.2 per cent, 18 to 24 months in 16.2 per cent, 24 to 30 months in 19 per cent, 30 to 36 months in 16.2 per cent, and 3 years and over in 5.4 per cent.

The most frequent symptoms were—diarrhoea in all cases, with an average duration of 17.3 months, tongue lesions in 39 including 19 with active ulceration, loss of weight in all cases, average loss 28 lb, abdominal distension and flatulence in all, severe in 20 cases. Less constant symptoms were loss of appetite, nausea and vomiting, and cramps in the legs. Anaemia was not a striking feature, the average red cell count was 3.94 million, and the colour index 1.06. Faecal fat was estimated in 22 cases, the total fat was 37.12 per cent of dried faeces and the split fat 28.64 per cent. Split fat was therefore 77.15 per cent of total fat.

At the end of 2½ to 3 years the author was able to trace 34 patients. All were in full work. Twenty nine had gained weight and the average gain in weight of the 34 patients was 24 lb. All patients stated that they were free of diarrhoea, but 23 had had some diarrhoea, usually of a very transitory nature, at some time since their return to Britain. 6 men had had 4 or more attacks of short duration and 3 others one attack lasting 1 to 2 weeks. Eleven complained of ulcers on the tongue at some time. Occasional attacks of abdominal discomfort and distension were complained of by 6 men and frequent attacks by 3 others. Only 3 men considered that their energy was still somewhat impaired.

LOX, H. J. A Comparison of Pteroylglutamic Acid and Liver Extract Maintenance Therapy in Sprue. *New England J of Med* 1949, May 10, v 240 No 20, 801-3.

There have been conflicting reports on the haematological response of sprue to treatment with synthetic folic acid. Seven patients with sprue, all previously treated for years dietetically and with liver and vitamin preparations, were given synthetic folic acid for at least a year. In general the effect was beneficial, in the majority of the patients there was a lessening of diarrhoea and a corresponding increase in weight, in spite of a daily oral dosage of 60 mgm. of folic acid sufficient to increase to 100% the plasma folic acid levels, and other manifestations of severe sprue. The proved as non-positive to purified liver preparation as to folic acid, but responded to massive intravenous doses of synthetic liver preparation. The requisite dose of folic acid in the cases which benefited by the latter was found to be from 15 to 30 mgm. daily, or 5 mgm. only daily. This deficiency of folic acid is not a simple one. In spite of the demonstrated deficiency of folic acid in the plasma, the liver preparations were found to be more effective than folic acid in the treatment of the disease.

HAEMATOLOGY

CORRECTION

In his abstract of a paper from the *Lancet* by LEHMANN on Macrocytic Anaemia in Central Africans [this *Bulletin* 1946 v 46 (34)] the abstracter queries the use of the word "coctile." The word should in fact have been "precoctile." Since the paper was written a note has appeared in the *Lancet* of 1949 January 22nd, 199 in which it is explained that the word "coctile" was printed in the original article through a series of errors, and the editorial explanation goes on to state —

"Dr Lehmann's paragraph introducing the word should have read as follows —

"The reticulocytes and cells in the early postreticulocytic stage are here called precoctile cells. By precoctile blood picture is meant one due to a condition where large cells are produced in regeneration, the macrocytosis not being due to a disturbance of bone-marrow function by the absence of essential nutrients but being, on the contrary, caused by a hyperactivity of the marrow which leads to an emission of slightly unfinished cells (coctus=fully mellowed). To call these cells immature might suggest an inhibition of cell production at the nucleated stage and the term regenerative would not differentiate from a state where regeneration proceeds without macrocytosis.

Stated to be the first recorded case in Australia.

SCHWARTZ, S. O. & MARIN J. Mediterranean Anaemia in the Negro. A Report of Four Cases and their Families. *Blood* 1949 June v 4 No. 6 706-14 figs. 28 refs.]

Four cases of Mediterranean anaemia are reported in Negroes.

"The hematologic and clinical findings of available relatives are presented.

The disease in the Negro resembles the condition as found in people of Mediterranean ancestry in every particular."

VAN DER SAR A. De sikkelcellekte. Sickle-cell Anaemia. *Ned. Tijdschr. v. Geneesk.* 1949 June 4 v 83 (1) No. 23, 1807-74 5 figs. on pl. (Refs. in footnotes. English summary)

A full review of the literature of sickle-cell naemia is given and the symptomatology reviewed. Three negro sisters are then described all of whom had sickle-cells in the blood and had recurrent crises with fever, icterus and anaemia. All have so far recovered from their crises. The family history is given both parents had sickle-cells in the blood without symptoms. Of the ten children, all five sons were free from the disease, two daughters had latent sicklaemia and three daughters had recurrent sickle-cell crises.

These cases occurred in Curaçao. Blood examinations were carried out on 2,498 inhabitants, of whom 10.7 per cent. had sickle cells in the blood, 8.4 per cent. males and 1.3 per cent. females.

Striking changes in the bones are seen in these cases, mainly thinning of the cortical bone, osteoporosis and variations in density. The skull often shows a phenomenon termed "hair on end sign" or "*signe en brosse*", the outer table disappearing and the diploë appearing striated.

The spleen also shows marked changes, including calcification. Treatment is symptomatic. Splenectomy has proved disappointing. *A L Winner*

VENOMS AND ANTIVENENES

CECCALDI, J, TRINQUIER, E, ARNOULT, H & PELLISSIER, A. Sur quatre cas d'envenimation par morsures de "vipéridés" observés à l'Institut Pasteur de Brazzaville (Afrique Équatoriale Française) [Four Cases of Snakebite at the Brazzaville Pasteur Institute.] *Bull Soc Path Exot* 1949, v 42, Nos 1/2, 38-43

These four cases occurred among the employees at the Pasteur Institute, Brazzaville, French Equatorial Africa. One was bitten by a *Bitis arietans*, one by *B. nasicornis*, and two by *B. gabonica*. The symptoms were very similar in kind, though varying in degree. Three were bitten on the right thumb (one of them twice) and the other on the left hand. The symptoms were severe pain, rapid and extending swelling and, later, haemorrhage. All recovered in a few days, but in the case of the first there was some residual weakness of the muscles and stiffness of the forefinger, though 6 years had elapsed. One of the *B. gabonica* was only 3 weeks old, but the effects of its bite were very serious and a second injection of antiserum was called for. The dose given was 20 cc. In the case of the attendant bitten by *B. arietans*, the antiserum was obtained from the South African Institute for Medical Research, one of those bitten by a *B. gabonica* received the locally prepared antivenin, for the other two the source of antivenin is not mentioned but would appear to have been the Johannesburg Institute serum. The locally prepared serum is polyvalent for the Viperidae *B. gabonica* and *B. nasicornis*, and the Colubridae *Naja nigricollis* and *N. melanoleuca*. Other local snakes are *B. arietans*, *Causus rhombeatus*, *A. squamiger*, *Dendraspis* and *Boulangerina annulata*, but these are rarely caught so that their antivenins are prepared locally only occasionally.

ABALOS, J W. Cuales son los animales venenosos de la Argentina? [What Poisonous Fauna are there in the Argentine?] *Universidad Nacional de Tucuman. Instituto de Medicina Regional. Publicación No 481* 1949, 24 pp, 16 figs

This article names the commonest of the venomous animals—including in this term fish, snakes, spiders and scorpions—to be found in the Argentine. The author adds a few remarks on some of these, but of an elementary character.

In the section on snakes the author indicates by diagrams the different dentition of the aglypha, opisthoglypha and proteroglypha and then proceeds to name the chief species, namely, *Crotalus terrificus*, 7 species of *Bothrops* (locally known as *jararã*) of which the chief are *B. atrox*, *B. colliara*, *B. jararaca* and *B. jararacussu*, the others being *B. alternatus*, *B. neuwiedi meridionalis* and *B. ammodytoides*, three species of coral snake, *Micruis lemniscatus*, *M. corallinus* and *M. frontalis*, the first of these found all over the Argentine. There are also several species of "false coral snake", very like the true venomous ones, but the peculiar colour markings are only on the dorsum whereas in the

true Coral snakes the markings go quite round the body. A line map shows clearly the distribution of the snakes mentioned. There is also the "black snake" *Pseudoboa olivacea* a mortal enemy of the poisonous snakes which it fights relentlessly and eats when it has subdued them. It is coloured a slaty black dorsally, dull white ventrally with some red scales on the sides. It is about $2\frac{1}{2}$ metres in length, is slender and agile. It does not attack man and does not resent being handled.

Of spiders the most venomous is *Latrodectus* especially *L. mactans* (the Black Widow) and *L. geometricus*. There are says the author 40 species of scorpion in the Argentine but the only one mentioned by name is *Tityus tritatus* which gives a painful sting but without sequelae. The venom of some "appears to have an analgesic effect." The whole subject of scorpions and their venoms in the Argentine needs to be studied.

DI PIETRO A. NIRO F. L. & COSTA L. P. Histoplasmosis o reticulohistiocitosis paratuberculosa con localización lingual. [Histoplasmosis of the Tongue.] *Rev Asoc Med Argentina* 1949 May 15-30 v 63, No. 633/634 223-31, 6 figs. 27 refs.

The English summary appended to the paper is as follows:—

"In a man 55 years old, the authors report the clinical and histopathological study of localized Darling's histoplasmosis or paratuberculous reticulohistiocytosis of the tongue by *H. deplumans* *fruticum*."

"This case would be the 4th of histoplasmosis in Argentina."

BASE H. E., SCHOMER, A. & BERKE, R. Question of Contagion in Coccidioidomycosis. Study of Contacts. *Amer Rev T Vermon* 1949 June v 54, No. 6, 637-5.

It is probably true of all the systemic mycoses, caused by "dimorphic" fungi, that infection is not transmitted directly from man to man except in rare accidental cases associated with post mortem examinations or surgical operations. However ROSENTHAL & ROUTEN (this *Bullet* 1949 v 43, 467) by instilling directly into the bronchial tree of guinea-pigs the infected sputum and pus from human cases of coccidioidomycosis, succeeded in infecting the animals and thus they contended was evidence of the probable direct transmissibility of the disease. The present paper which is a timely relation of the view of Rosenthal and Routen as to natural infection in man is concerned, records the careful observations made on 11 intimate contacts

(wives, sons, daughters, brothers, sisters, etc) of 7 ex-soldiers suffering from persistent coccidioidal infection, six with pulmonary cavitation and the seventh with disseminated disease involving both skin and lungs. The periods of exposure of the contacts ranged from 6 months to 5 years, and all the persons concerned were resident in New York City, far removed from the endemic centres of the disease. The observations on the contacts, which included repeated coccidioidin skin tests and X-ray examinations of the chest, yielded no evidence whatsoever of infection.

TROPICAL ULCER

RAO, V R, KINI, M G & SUBRAHMANYAN, K S **Tropical Ulcers in Madras City** *Indian Med Gaz* 1949, Mar, v 84, No 3, 88-92, 15 figs on 3 pls [10 refs]

This article is based on 38 cases of tropical ulcer treated at the Stanley Hospital, Madras, from December 1946 to the end of February 1948. No age was immune but most of the patients were below 30, and 32 were males and 6 females. Those employed in hard labour and living in insanitary conditions were more prone to this condition than others (19 out of 38 cases). Most of the patients had a history of a fortnight to a month's duration and the general experience was that the maximal incidence occurred during and after the monsoon months (in 1947 the monsoon failed in Madras). Fifteen patients had multiple ulcers and there were 60 ulcers in 38 cases, one patient having as many as eight. Except in rare instances the ulcers were found below the knee, and were "of the size of a pea to that of the old silver rupee or even bigger in a few cases". They were very painful and acutely tender, and the general condition of almost all the patients was poor.

Fusiform bacilli and *Treponema vincenti* were found in most cases, but one showed only spirochaetes and a mixed infection of staphylococci, streptococci and *Ps pyocyanea* without fusiform bacilli [was this a case of true tropical ulcer?]. The culture medium used consisted of nutrient broth 100 cc, agar 1.5 gm, sterile defibrinated human blood, 25 cc. Difficulty was found in obtaining pure cultures by surface inoculation. In 13 cultures fusiform bacilli were grown in 6 cases.

On admission every patient was given a wash with sterile normal saline and thereafter a saline dressing was applied for 24 hours, during treatment repeated study of the organisms was made. Out of 60 ulcers, 48 were treated with penicillin in a strength of 1,000 units in one cc of pyrogen-free distilled water, this was with a Holmspray and the ulcer covered with a sterile dressing. With full compression of the rubber bulb the amount of penicillin sprayed amounts to 270 units. The dressing was changed once daily and all cases were treated as out-patients. Penicillin was discontinued as soon as the ulcer began to heal and the discharge became scanty, thereafter a thiazamide paste or a 1 per cent aqueous solution of gentian violet was used. Large ulcers took an average of 28 days to heal and the average amount of penicillin required for a case was 1,300 units (maximum 7,000). With 2 or 3 dressings even the worst cases were relieved of pain and the discharge was lessened. Eight ulcers were dressed with Marfanil powder (para amino methyl benzene sulphonamide hydrochloride). When *Ps pyocyanea* or *Proteus* was present response to penicillin was poor, but Marfanil was found to be effective. The cost

Marfanil is high and penicillin is regarded as the drug of choice in the ordinary case. [No reference is made to any attempt to treat the general condition of the patient.]

MISCELLANEOUS DISEASES

- SPITZER H. Essential Hypertension on the Island of Curacao. *Ann. II Intern. Med. & Surgery* 1949 Apr., v. 3 No. 4 133-5.

The incidence of hypertension is very high both in the coloured and indigenous white population in the island of Curacao and this investigation was done to determine the relationship between constant dehydration and hypertension, the study being based primarily on an examination of school children. Most of the children were coloured, they were of both sexes between the ages of 6 and 18, and of average health. More than 1,000 diastolic and systolic readings were made by the auscultatory method and 888 school children were examined; the remainder were adults, most of whom had hypertension.

School children. The readings were based on the systolic level as it was found that the diastolic rise followed the systolic (for some delay). The degree of hypertension was striking: thus 7 children between the ages of 10 and 18 had a blood pressure of over 160 mm. while 2 aged 6 years had one of 130-139 (systolic). In all the age groups the average was well above the normal. Over 100 blood volume estimations were done by the Congo Red method, which gave consistent results on repeated application to the same patient and there was correlation between deficit in blood volume and increase in blood pressure.

Precipitation per year in Curacao averages 20 inches and there is continuous sweating, although not comparable to the amount seen in desert area. Hypertension in Curacao does not appear to be related to race as white people born on the island or who had immigrated in infancy also showed high incidence of this condition.

The author's conclusions may appear debatable and the observations should be repeated in other parts of the world with a similar climate.

C. F. Sherrin

- DIEZ DE URDIA IRI A. & ESTRADA BERG J. Ecthyma. Scleroma. *U.S. Clin. Mexico*, 1949 May 25 v. 29 No. 580 187-9 17 figs.

The authors prefer the term scleroma to chancroid because the disease attacks other parts than the nose. In one record of 338 cases the local cords were attacked in 18.4 per cent., the upper part of the larynx in 12.9, the lances in 4.1 per cent. The accompanying *Ehrlichia bacillus* or *Klebsiella rhinoscleromatis* has not been proved to be the actual cause because experimental inoculation has so far been negative.

Pathologically the authors recognise three stages: 1. Atrophic phase in which the secretion contains the organism. 2. Nodular in which the tissue shows Mikulicz cells and Russell bodies and there is infiltration of the nasal cartilage and, perhaps pharynx and larynx. 3. Cicatricial. Scleroma and carcinoma may coexist. The treatment suggested comprises taroacetic

with results at best very dubious, X-rays and radium, and streptomycin, 0.5 gm morning and evening, to a total of 30-40 gm. After a week of this, symptoms of deafness, tinnitus and vertigo are likely to arise. Four cases are mentioned, but with little detail, in two, operative treatment—extirpation—was carried out, in the other two nothing is said about treatment. There are good photographs of this horrible condition [see this *Bulletin*, 1949, v 46, 872] H Harold Scott

PRIEST, W M Acute Meningo-Encephalitis of Uncertain Origin in West African Troops *Trans Roy Soc Trop Med & Hyg* 1949, May, v 42, No 6, 581-96, 4 figs (3 on 2 pls) [29 refs]

There is a large and growing literature on the neurotropic viruses but little is known about their clinical manifestations in the tropics and few reports have appeared on this subject. The 10 cases here reviewed, mainly from the clinical standpoint, and coming chiefly from Nigeria, were in-patients aged between 19 and 36. Nine occurred during December to March, the driest and hottest time of the year. The cause was believed to be a filterable virus, although as experimental animals were unavailable, definite incrimination of a specific virus was not possible.

The cases described are all examples of an acute illness with sudden onset, fever, headache and in some instances, meningismus, cranial palsies, hemiplegia and monoplegia. A variable pleocytosis was present in the cerebrospinal fluid together with a marked rise in protein content. Xanthochromia was present in 5 instances (3 fatal). Six of the cases were fatal, and the author considers that the facts suggest infection with a neurotropic virus.

Trypanosomes were not found in the cerebrospinal fluid and no glandular enlargement was present. Of the first 8 patients the 2 who survived received no trypanocidal treatment, and in those who died there were no signs of trypanosomiasis.

A positive blood Kahn is so frequent in West African patients that its presence carries very little weight. Cerebral malaria is rare in West African troops, and moreover all these patients were given parenteral quinine or mepacrine without therapeutic effect.

No evidence of tuberculosis was found in the meninges or elsewhere in any of the fatal cases. None of the patients had been recently vaccinated.

The incidence of neurotropic viruses in the tropics is now increasingly well known. HAMMON and REEVES [*Bulletin of Hygiene*, 1946, v 21, 14] state that evidence is accumulating that there are a large number of such viruses of man and other animals (arthropod-borne) of "world-wide distribution and no small importance". Search for immune bodies to West Nile virus has shown their presence in the sera of Africans over a wide area of Central Africa. Others such as that called "Semliki Forest virus" [SMITHBURN and HADDOW, this *Bulletin*, 1945, v 42, 320, 1946, v 43, 859] have been identified, but little is known of the diseases caused by them in man. C F Shelton

ALAIN M, SAINT-ETIENNE, J & REYNES, V La melioidose. Considerations étiologiques, cliniques et pathogéniques à propos de 28 cas. [Aetiology, Clinical Features and Pathology of 28 Cases of Melioidosis] *Méd Trop* Marseille 1949, Mar-Apr, v 9, No 2, 119-42, 10 charts [Bibliography]

The authors report 28 cases of melioidosis from Cochinchina and give full clinical details of 10 cases which illustrate the protean manifestations of the

acute subacute and chronic forms. Nineteen patients are known to have died but a number could not be traced—three have survived for four years after clinical cure. Treatment appears to have been largely surgical.

In no case was the source of infection ascertained and the authors are sceptical of the rodent origin of the disease. Over 20 000 rodents have been examined in Cochin China and many thousands of cultures made from them—only one strain of *Pf. whitmorei* has been isolated. Unlike plague the disease is more prevalent in Europeans than in the indigenous population who are in closer contact with rats. The organism has once been isolated, along with *P. pyocyanea* from the blood of a shaved guinea pig immersed in contaminated water. The authors discuss the possible origin of *Pf. whitmorei* considering particularly whether it might be a sudden mutant or an organism usually saprophytic and attaining virulence in debilitated persons. All of their infections arose in subjects debilitated by surgical operations or febrile illnesses, and in some the disease actually appeared after the patients had been a considerable time in hospital. The view is taken that *Pf. whitmorei* may be a virulent variant of *P. pyocyanea* to which it bears some morphological, cultural and biological resemblance (a view which has previously been expressed by a number of French workers). One worker has demonstrated that certain strains of Whitmore's bacillus produce a soluble green fluorescent pigment in synthetic medium.

This paper contains the most complete list of references on melioidosis known to the abstractor.

PROTOZOOLOGY: GENERAL

BROCCA E. Osservazioni sulla posizione d'istematica del *Trotoplasma*. The Place of *Trotoplasma* in Nature. *Riv. di Parassit.* Rome 1919 June v. 10 No. 2, 73-92. (246 refs.) English summary (9 lines)

More than 40 years ago Nicolle and Manrooux described a protozoon in a rodent in North Africa and named it *T. plasma gondi*. Others remarked on its likeness to *Leishmania* others again to *Encephalitozoon*. Cases of human infection have been reported by Castellani in Ceylon but Wenyon has cast doubt on these. In short there seems to have been a certain degree of confusion between *T. plasma*, *Encephalitozoon*, *Sarcoplasma* and *Sarcosporidia* and the place of *T. plasma* in nature is yet to be determined.

From a consideration of this vexed subject the author concludes: 1. that *T. plasma* if it is to be regarded as a protozoon has simple morphology (as described in the textbooks) is non-motile but endowed with gentle writhing motion (scintillamento) capable of infecting many vertebrates penetrating and multiplying in the tissues. 2. It differs from *Rhizopoda*, *Flagellata*, *Ciliata* and *Sporozoa*. 3. the reputed species *T. canis*, *T. felis*, *T. muris*, *T. hominis* etc. merely indicate that *T. plasma gondi* has been found in different hosts and that there is only one valid species. 4. the genera *Encephalitozoon* and *Sarcoplasma* have no characters sufficiently different to separate them from *Trotoplasma* and therefore 4. one cannot accept the species of *Encephalitozoon* e.g. *E. cuniculi*, *E. brevis*, *E. felis* etc. and *T. plasma* and *Sarcosporidia* are only differentiable morphologically and biochemically though they have certain characteristics in common. H. H. Goldie

ENTOMOLOGY AND INSECTICIDES GENERAL

PICAUD A. Observations sur la repartition des gîtes larvaires de moustiques sur le territoire d'une ville de la banlieue parisienne Saint-Maur-des-Fossés (Seine) en 1948. [Observations on the Distribution of Mosquito Breeding Places in the Town of St. Maur-des-Fossés (Seine) on the Outskirts of Paris in 1948. *Rec. Trav. Inst. Nat. Hyg. Paris*, 1949 Tome 3 v. 3 871-8, 1 fig.

— Expériences relatives à la possibilité d'un contrôle du pullulement des larves de moustique (*Culex*) dans les égouts d'une ville de banlieue (St. de Saint-Maur-des-Fossés Seine) [Experiments in the Control of Mosquito Larvae (*Culex*) breeding in the Street Sewers of a Suburban Town (St.-Maur-des-Fossés, Seine)] *Ibid.* 879-91 5 figs.

These papers are concerned with the control of house-haunting *Culex* in St. Maur-des-Fossés on the outskirts of Paris. Little or no breeding was observed in pools, ponds, marshes, cesspits, lakes, waterways, nor in boats anchored in the river. But extensive breeding occurred in the precipitation chambers at different points of the street sewer system. This type of chamber is common in Paris and in provincial towns. In summer larvae and pupae occur in large numbers in these chambers; adults are found on their walls and also in houses. In winter only a few aquatic stages remain in the chambers and the adult females are found hibernating in large numbers in cellars, caves and stables.

The author discusses the difficulty of treating these breeding places with insecticide. The chambers are subject to recurring vigorous water flow; they often contain a great amount of debris of all sorts from the streets and spider webs are commonly plentiful. Periodic dusting and spraying was consequently found to be unsatisfactory. Complete control was obtained, however, by depositing a small block of plaster impregnated with 50 cc. of a 5 per cent DDT solution in keroline in each precipitation chamber. Four treatments in this way between May and September are proposed; a probably adequate to control the mosquito during its active breeding season.

Culex pipiens larvae were found during a survey of ponds and ornamental lakes in the town but no specific identification given of the *Culex* breeding in the precipitation chambers. D. S. Bertram

KING W. A. & HOOCHSTRAL H. Species of *Ides* (Family of the paper "Group in the Australasian Region (Diptera, Callitidae). *Proc. Entom. Soc. of Australia*, 1946 48 v. 4 134-57 3 figs.

CARTER H. F. & A. J. SIMPSON J. Observations on Sandflies (*Phlebotomus*) in Delft Island, North Ceylon. (*Trop. Med. & Parasit.* 1949 Apr v. 43 No. 1 62-73 2 figs. & 1 map.

Two visits were made to Delft Island (Ceylon) one from July 22nd to August 19th, 1947 during the dry season and the second from January 9th to 31st 1948, at the end of the wet season.

Collections of adult *Phlebotomus* were made both indoors and outdoors in different parts of the island and by the use of land at baited traps, light traps, oiled paper traps or by spraying indoors with pyrethrum spray and collecting the sandflies from a white sheet laid over the floor. No possible breeding places was examined by Stot in detail. 1

The following species were taken *Phlebotomus argentipes* (3,227 ♀, 853 ♂), *P. antennatus* (27 ♀, 45 ♂) *P. babu* (?) (9 ♀, 4 ♂), and 1 ♀ and 6 ♂ of uncertain identity. *P. antennatus* had not previously been recorded from Ceylon and *P. zeylandicus*, common in parts of the main island of Ceylon, was not found on Delft Island.

P. argentipes, the predominant species, was more abundant in January than during July and August. They occurred in about the same densities during January in stone-and-mud houses and in those built of coconut palm leaves but they were more common in the stone-and-mud houses in the dry season (July–August). Males usually formed less than about 23 per cent of the catches but in two instances much higher percentages (68 and 75.5 per cent) of males were taken. Females, engorged apparently with blood, were caught during both the dry and wet seasons, but those with ripe ovaries were more numerous in the wet season.

Of 148 possible breeding places of *Phlebotomus* examined 19 were positive for immature stages of the fly. The positive sites were crevices in the floors and plinths of houses, the soil at the edges of refuse heaps and at the base of stone walls. In January, 18 out of 110 sites contained larvae, larval skins, or pupal cases and of the 38 sites examined during July and August only one, containing one pupa, was positive.

Breeding appears to be restricted in the dry season (July and August).

Captive females of *P. argentipes* deposited 95 eggs in the laboratory, the larvae which hatched from these eggs were bred out in moist soil and crushed guano and faeces and 15 ♀♀ and 10 ♂♂ were obtained 28–35 days after the original oviposition. The temperature of the laboratory varied from 25° to 28°C and the relative humidity from an afternoon mean of 66.6 per cent to a morning mean of 74.4 per cent. The temperature of the breeding medium at one inch below the surface was consistently 30°C.

LUSCHER, M. Continuous Observation of Termites in Laboratory Cultures. *Acta Tropica* Basle 1949, v 6, No 2, 161–5, 2 figs

The author describes a technique which he has employed successfully for maintaining colonies of termites in captivity and under conditions in which constant observations can be made.

One wall of the nest consists of a clean photographic plate (12×9 cm). The other wall is made in sections with ordinary microscopic slides, the slides being separated from the plate by narrow glass slips arranged to form the sides, bottom and top of the nest. The thickness of the glass slips is only sufficient to give the termites room to move freely between the plate and the slides. The space allowed varies with the species of termite but it is between 1.5 and 4 mm. The lower quarter of the nest is partly cut off from the rest of the chamber by two transversely arranged glass slips. These, however, do not meet in the centre, thus leaving a communicating gap between the upper and lower compartments. The lower chamber contains damp cotton wool. Glass wool plugged into the central gap draws up the water and maintains a high humidity in the nest proper. The termites, together with fine clean sand and selected wood, are accommodated in the upper compartment. All junctions of the glass slips, the plate and the slides are sealed with wax except at one point where a small crack is left open for aeration.

Nests of *Calotermes flavicollis*, *Reticulitermes lucifugus*, *R. hesperus* and *Zootermopsis angusticollis* have been maintained in a healthy reproductive state for up to fourteen months.

Replenishment of the water in the wool is necessary every four to six weeks. This is accomplished by removing the slide overlying the wool. As the slides

covering the nest become obscured by accumulating debris and Larces they are removed and replaced by new slides.

Apart from observations on the termite castes and so on, these nests have been useful for extensive tests on the resistance of different woods to termite attacks.

SAUTET J LEVASSSEUR G VUILLET J ARNOUX R. Possibilités d'action directe et indirecte des ultrasons dans la lutte antilarvaire contre le paludisme la fièvre jaune et la dengue. Première partie Action biologique des ultra-sons sur les culcides (SAUTET LEVASSSEUR & VUILLET). [The Possibilities of controlling Malaria, Yellow Fever and Dengue by the Direct and Indirect Action of Supersonic Waves on Mosquito Larvae.] *Rec Travaut Inst Nat Hyg Paris* 1949 Tome 3 v 3, 997-1020 17 charts & 3 figs. Deuxième partie Action des suspensions le DDT et autres corps traités par les ultra-sons (SAUTET ARNOUX LEVASSSEUR & VUILLET). [The Action of Suspensions of DDT and other Substances Irradiated by Supersonic Waves.] *Ibid* 1021-8.

In the first paper the authors have investigated the effectiveness of super-sonic waves for the destruction of the eggs, larvae and pupae of some culicine mosquitoes and of *Anopheles maculipennis*. Under experimental conditions in which the impact of the waves on the organism is ensured for the whole of the exposure period death may follow immediately or after a period of a few hours. Immediate deaths are caused in late larval stages by excystation whereas in the young stages the tissues of the larvae are disintegrated. Eggs are ruptured by effective treatments. Some eggs which survived treatment gave rise to larvae which developed more rapidly than control larvae. Exposures to 1,200 mA for two seconds or to about 300-400 mA for thirty seconds are effective but this effectiveness varies somewhat with the stage and the species of mosquito.

In experiments in which the waves were not evenly reflected throughout small breeding dishes of about one litre capacity some larvae died immediately but others survived for up to seven days even after 10-15 minutes exposure of the water to 1,200 mA.

Moultine, pupation and the emergence of adults follow after inadequate treatments.

There is little indication that the type of apparatus employed (this is described and figured) is likely to be of practical value for the control of mosquitoes under field conditions.

The second paper deals with a few small experiments on the effectiveness of DDT, pyrethrum and hexachlorocyclohexane (benzene hexachloride) against culicine larvae. Only five larvae were used in each experiment. Irradiation with supersonic waves is an added factor in some of the tests but it is not in the reviewer's opinion, clearly shown that this materially improves the action of the insecticides.

LABORATORY PROCEDURES

COUDERT J & JUTTA P. A propos des methodes d'enrichissement des milieux. On Methods of Enrichment of the Stocks. *Bull Soc Path Exot* 1949 v 42, No. 34 111-14.

The authors find that direct examination of the stools is often insufficient and that some enrichment method is necessary. The essential conditions for such method are that —

- (1) A large number of parasites should be concentrated in the least possible volume ,
- (2) the maximum amount of inert matter should be eliminated ,
- (3) the morphology of the cysts and ova should be maintained

Several methods in common use are discussed. The method of CARLE and BARTHÉLÉMY (1913) takes too long and entails the use of two reagents. Further, the formalin alters the shape of cysts. The method of YORK and BIDEGARRY gives good results but has the same disadvantage of being long and in addition requires a 30 per cent solution of saccharose, a material difficult to obtain at present.

The method of TELEMANN modified by Garin eliminates some of the disadvantages of the former of the above methods. The technique that the authors suggest is a modification of this method. It is as follows —

A "walnut" of faeces is added to 100 ml of water. The solid matter is pulverized with an agitator and a fine emulsion obtained. The material is allowed to settle for one minute. In an ordinary centrifuge tube are placed 5 to 6 ml from the superficial layer of the emulsion and 1 ml of hydrochloric acid is added. The whole is shaken. 2 or 3 drops of toluene are added and the preparation is again shaken vigorously. The tube is filled with ether. The whole is shaken and centrifuged slowly for 3 or 4 minutes.

The sediment is examined between a slide and coverslip.

The order in which the materials are added is important.

The method has been used for 6 months in the *Laboratoire de Parasitologie de Lyon* and over 500 stools have been examined. It was found very satisfactory even in the examination of icteric stools which usually present difficulties.

PICK, F. Nouveaux dispositifs pour la technique de la coproculture [New Methods of Coproculture] *Acta Tropica* Basle 1948, v 5, No 4, 354-7, 4 figs.

Pick describes and illustrates some new methods of recovering nematode larvae from faecal cultures. These are modifications based on the principle involved either in the Baermann technique or on the Petri dish technique and as they require a minimum of laboratory apparatus are useful in routine examinations. The illustrations should be seen in the original.

REPORTS, SURVEYS AND MISCELLANEOUS PAPERS

COLONIAL OFFICE Colonial Research 1948-49 Reports of the Colonial Research Council, Colonial Products Research Council, Colonial Social Science Research Council, Colonial Medical Research Committee, Committee for Colonial Agricultural, Animal Health and Forestry Research, Colonial Insecticides Committee, Colonial Economic Research Committee. Cmd 7739 134 pp 1949 London H M Stationery Office [2s]

This Report comprises 7 sections, each an annual report (1948-49). The bodies represented are Colonial Research Council, Colonial Products Research Council, Colonial Social Science Research Council, Colonial Medical Research Committee, Committee for Colonial Agricultural, Animal Health and Forestry Research, Colonial Insecticides Committee, Colonial Economic Research Committee. Of these, the reports of the Colonial Medical Research

Committee and the Colonial Insecticides Committee will be of most interest to readers of this *Bulletin*.

The list of schemes approved in the financial year 1948-49 for grants under the Colonial Development and Welfare Acts is most impressive. The sum covered in this list is £1,852,169 and the allocations made since the inception of the organization after the first Act of 1940 have reached the figure of £5,913,708. The actual issues in relation to the research schemes (many of which are planned to extend over several years) are of course much less, £1,579,418 but the money for the remainder is available and in due course the work which it represents will be accomplished. Medical research is well represented in this list but no individual item commands the big sum given to certain projects of fishery research and of agriculture and forestry research. Nevertheless there are many medical projects of considerable size and very varied interest.

The East African Medical Survey, now begun in Tanganyika Territory should provide useful information on the vital statistics and common diseases of the Africans living under rural conditions, provided that it is carefully carried out for a long period. Some readers will remember the survey conducted in the Bahama district 20 years ago by Dr A. R. Lester which was abandoned when it became evident that the outbreak of trypanosomiasis was interfering grossly with the Africans and their cattle. It is to be hoped that this history will not be repeated.

The virus research laboratories in Uganda and Nigeria are to be taken over completely from the Rockefeller Foundation (which has partly financed them) in the near future and the laboratory at Freetown will be taken over from the Liverpool School of Tropical Medicine. The staffing of these laboratories has presented difficulties but when these are surmounted there should be opportunities for much fundamental research. Apart from these there were several projects in being: the Nutrition Research Station in the Gambia, where improved methods of farming are being tried; research on malaria in North Borneo, Malaya and East Africa, on scrub typhus in Malaya, relapsing fever in Kenya and on physiology in Uganda and Nigeria. The Report itself is much more than a catalogue of these efforts, in that it gives considerable detail of some of the work. For instance the recommendations on dosage of proguanil (paludrine) made by the team working on a West African strain of *P. falciparum* at Horton are given in full and there is much detail of the results obtained in the treatment of schistosomiasis with Surcil D and of scrub typhus and typhoid fever with chloromycetin. Similarly the investigations into transmission of yellow fever in Uganda and scrub typhus in Malaya are summed up (so far they have gone) in such a manner that an administrative officer could obtain a reasonable grasp of the subjects. These accounts add very greatly to the interest and value of the Report.

The Report of the Colonial Insecticides Committee is equally interesting, reference being made to the mosquito eradication experiment in Cyprus and Mauritius, to the various malaria experiments and to the work being done against tsetse and other flies. Some of the work of this Committee and of the Colonial Insecticide Research Unit, Uganda, concerned with agricultural problems.

Charles Wilcock

COMMUNALITH I THITE F I (OMI) S Report of the Fifth Commonwealth Entomological Conference 22nd-30th July 1948. pp. - 112. 1949. Dnc London 41 Queen G 1 W 7 7 8J

Forty-six delegates and official observers attended the Fifth Commonwealth Entomological Conference held from the 22nd to the 30th July 1948 in London.

Micro-organisms, 38 Old Queen Street Westminster London, S.W. 1 and the "Catalogues" are available free on request from the Director Laboratory Animals Bureau, Royal Veterinary College Royal College Street London, N.W. 1

It is recognized that the particulars so far collected are probably incomplete and institutes which are maintaining cultures and are willing to co-operate are asked to send details of their collections to the appropriate address for inclusion in future lists.

R. L. Sheppard

[INDIA. Annual Report of the Public Health Commissioner with the Government of India for 1946. MEHTA, J. N. Director General of Health Services, Govt. of India] 117 pp., 1 folding map, 1948. Delhi: Manager of Publications. Rs 2 12 or 4 (6d)

This Report dated November 1947 is signed by Dr Jivraj N. Mehta, who was the first Director General of Health Services of the new Government of India established in August 1947. It closely resembles the report for 1945 except that the Arms of the new Government on the cover replace the Royal Arms.

The only statistical table that is provided deals with the birth death and infant-mortality rates of the parts of India still described as British India. These statistics have always been regarded as quite untrustworthy for most of the Provinces and in view of the disturbed conditions prevailing in 1946 they are not likely to be any more reliable than formerly. Startling variations occur in the figures for different Provinces—for example the birth rate is shown as 18.0 in Sind and 37.7 in the adjoining Province Punjab—the death rate is shown as 8.7 in Sind and 28.9 in Central Provinces. For what they are worth the figures suggest that the birth rate has risen appreciably from the low rates recorded during the years 1941-1945.

In the body of the Report figures are given for three rural areas in which experimental Health Units have been working for several years. These figures are likely to be fairly reliable because the reporting agent have been under supervision of the staffs of the Units, and although they deal with small samples of the population—about 50,000 each—they are significant in showing what has happened in typical areas provided with modest health organization. If similar results were to follow the establishment of such Units throughout India the rate of growth of population would be greatly accelerated.

	Birth Rate		Death Rate		Infant-Mortality	
	1949	1945	1946	1945	1946	1945
British India	28.4	27.3	18.4	1.5	125.8	150
Najafgarh Health Unit (Delhi Province)	45.7	48.6	1.5	4.0	116.7	151.7
Singur Health Unit (Bengal Province)	47.5		16.5		120.2	
Puranasalle Health Unit (Madra Province)	34.3	22	1.9	2.5	162	10.8

The only reference to the population problem in the present Report is the following statement by Dr Mehta in his introductory remark: "During recent years India has gradually drifted into a position of overpopulation. The pressure of the increased population on the land is only one of the factors involved in such a situation."

This statement should be read in conjunction with remarks contained in the section on Nutrition from which it appears that food is still a major problem for 170 millions of the people and that the daily adult ration provided barely 1,200 calories—possibly the lowest intake of rationed food in the world. The total production of cereals in India is said to be 4,000,000 tons, only the

quantity needed being about 8,000,000 tons, the shortage was partly made up by importing 2,000,000 tons "and this was all that was available."

These statements suggest that to maintain the people of India in a moderate state of nutrition the food supply would have to be twice as great as the amount actually being produced in India, and that even if this huge increase could be made available a further progressive increase would be needed for the rapidly growing population

The most authoritative pronouncement on this appalling problem has been made by the Health Survey and Development Committee in their Report, dated 1946 [which was reviewed at length in this *Bulletin*, 1947, v 44, 252]

This problem of population and food supply is by far the greatest of all public health problems not only for India but also for most of the countries of the world. Competent experts have estimated that one-half of the world population are suffering from severe malnutrition and that one-half of the rest are undernourished

Public health workers everywhere, except in a few progressive countries are faced with a situation in which their efforts to improve health conditions, must inevitably fail unless a suitable balance can be established between the number of mouths to be fed and the food that is available. A tragic feature of the situation is that the more lives are saved by the control of infectious diseases the sooner will the food-supply position become acute

It may be argued that population control and food production are not subjects for which health organizations are responsible, but although this is technically true it would be a suicidal policy to remain silent and inactive spectators of the process of undermining the very foundations of the public health structure

What can be done is to make the problem a subject of study in every public-health curriculum and to organize a concerted effort to arouse both governments and peoples to a sense of the gravity of the situation and of the need for action to avert disaster

No apology is needed for calling special attention to the above problem, the rest of the Report is relatively unimportant, it deals chiefly with the incidence of the great infectious diseases, none of which was unusually prevalent in 1946

Cholera was less severe than in 1945, though some readers may be surprised by the statement that in Bengal "the incidence of the disease was even milder this year" when they go on to read that there were 27,710 deaths. Cholera inoculation was extensively carried out, in Bengal nearly 8,000,000 persons were inoculated

Plague was epidemic in some parts of the United Provinces where there were 18,199 deaths, also in Bombay, Bihar and Madras

Malaria was severe in Bihar, but not in any other province. Plans were made during the year for controlling the disease by DDT and paludrine [Proguanil]

Tuberculosis received special attention, reference is made to proposals to employ BCG vaccine as a control measure

Leprosy treatment and control on comprehensive lines was being planned in Bengal

Kala azar was not specially prevalent in any province, the only figures given are for Assam where 22,000 patients were treated

At a Conference of the Provincial Ministers of Health the recommendations of the Health Survey and Development Committee were accepted in principle as "objectives to be kept in view," but the programme for the first five years was regarded as "not within present financial resources"

A brief summary is given of the valuable research work carried out during the year—the chief subjects were malaria, nutrition, cholera, plague and leprosy.

The activities of the voluntary health organizations are described—these include the Red Cross and St. John Ambulance organizations, the Tuberculosis Association of India, the British Empire Leprosy Relief Association (India Council) and various provincial Maternity and Child Welfare Associations.

John H. D. Vargas

LOURENÇO MARQUES MOZAMBIQUE. Missão de combate as tripanosomíases. Relatório anual de 1947 (Mission for combating Trypanosomiasis. Annual Report for 1947) 132 pp. 11 maps, 3 graphs & 1 plan. [10 refs.] 1948.

The Mission was appointed in 1945 and its field of action is practically the whole Colony of Mozambique—the construction of the hospitals, dwelling houses and other works is expected to be completed by June 1949. The Chief of the Mission, Dr. Mário Augusto de Andrade e Silva, succeeded his predecessor Dr. Jacinto de Sousa on 1st April 1947. The Staff consists of 45 Europeans and 103 Africans—the former include 11 medical officers, 5 veterinary surgeons, a botanist and an entomological staff of 14 under the direction of Mr. H. E. Hornby, formerly the Director of Veterinary Services in Tanganyika Territory. The expenditure during 1947 was 6,228 600 escudos (about £67,000 at 100 escudos=£1).

The regions of the Colony where the Mission worked were divided into 9 medical sectors and 4 veterinary sectors—the former are all north of the Beira Mashonaland railway—5 being in Niassa province and 4 in the province of Manica and Sofala which borders on Northern and Southern Rhodesia. The 4 veterinary sectors occupy the whole of the southern part of the Colony from the Natal boundary to the Zambesi river—on the west they border on Swaziland, the Transvaal (the Kruger National Park) and Southern Rhodesia.

Inspection.—During the year Dr. de Andrade e Silva toured the Colony with Dr. F. Pires, the chief veterinary officer of the Mission or with Mr. Hornby or with both and inspected most of the sectors—a short description of these journeys is given.

Tsetse fly surveys.—The distribution of the 4 species of tsetse fly—*Glossina morsitans*, *G. pallidipes*, *G. brevipalpis* and *G. austeni*—found in the Colony is shown on several coloured maps, and brief notes of the position in the various districts are given in the text. *G. morsitans* infests most of the area from the River Rovuma (the northern boundary with Tanganyika Territory) to about 40 miles south of the River Save. *G. pallidipes* is widely spread in the provinces of Niassa and of Manica and Sofala. *G. brevipalpis* and *G. austeni* are shown in the eastern part of the *G. morsitans* area and also in the Maputo river region south of Lourenço Marques. In November 1946 Hornby surveyed the western part (Alto Limpopo) of the country between the Save and Limpopo rivers and concluded that, owing to the climatic conditions, the kind of vegetation, and the distribution of the game animals *G. morsitans* could not subside in this area (see this Bulletin 1948: 45: 584). His findings were confirmed by an aerial survey made by the botanist, the assistant entomologist and Dr. Pires in November 1947. Other surveys by Hornby included one of the east coast south of the River Save where conditions are suitable for tsetse flies, especially *G. morsitans* and *G. pallidipes* were found—preventive measures will be taken in this area (Goruro) in 1948. Another survey was in the Maputo district between Lourenço Marques and the Natal boundary—see this Bulletin 1948: 45: 1068.

Sleeping sickness—This is practically confined to the two provinces of Niassa and Manica and Sofala and nearly all the cases in the latter province occurred in the Tete district. There were 253 cases (4 in Europeans), 197 in Niassa province and 56 in the Tete district, an increase of 101 on the number (152) in 1946. The incidence was 1.2 and 0.7 per 1,000 of the population respectively and the highest local incidence was 4.3 per 1,000 in Moçimba da Praia in the extreme north. The population is mostly scattered in the bush in small groups of one or two families, which is unfavourable to the occurrence of epidemics, and the chief cause of the increase of the disease is the movement of people due to the great increase in agricultural and industrial labour. There are 8 hospitals and 13 (later 26) observation posts. Patients are treated with antrypol and tryparsamide. The usual prophylactic measures of mass examination of people, bush clearing, disinfection of vehicles and travellers on roads, were taken and 1869 prophylactic injections of antrypol were given.

Animal trypanosomiasis—The veterinary sectors were determined by the need to protect cattle from nagana in some parts and by the importance of other areas for animal husbandry. It was necessary to protect the Sul do Save province (south of the Save river) as it has the best conditions for the cattle industry and is the least infested by tsetse flies. Sector 1 (H Q Maputo) has splendid resources for cattle breeding, in Sector 2 (H Q Mambone at the mouth of the River Save) the right bank of the River Save and the area of Govuro must be kept under observation in regard to *G. morsitans*, Sector 3 (H Q Espungabera on the Southern Rhodesian boundary opposite Melsetter) between the Rivers Save and Lucite, is heavily infested with tsetse flies but has agricultural importance, and in Sector 4 (H Q Vila Pery on the Beira-Mashonaland railway) the largest European settlement in the Colony is established and a high proportion of the cattle are infected with nagana.

The nagana problem is very serious and is the greatest obstacle to the future economic and social development of the Colony, nearly two-thirds of the Colony is infested with tsetse flies and nagana occurs also in some parts where no tsetse flies have been found, and it is thought that mechanical transmission may be important. There are about 600,000 head of cattle of which 450,000 live south of the River Save, 100,000 in Manica and Sofala, 30,000 in Zambesi province and about 4,500 in Niassa province. The corresponding approximate figures for sheep are 30,000, 20,000, 4,500 and 4,000, for goats 75,000, 90,000, 9,000 and 90,000, and for pigs 20,000, 28,000, 4,500 and 4,500. These are shown on a graph. In the province of Sul do Save very few cattle belong to Europeans, from lack of interest, but this area is very favourable for animal husbandry. Except in the provinces of Sul do Save and Manica and Sofala (Angónia) the Africans do not keep cattle. Most of the cattle in the provinces of Zambesi and Niassa belong to large agricultural companies and in spite of periodic treatment of infected animals these companies have to import cattle to make up their losses.

The commonest species of trypanosome in cattle, sheep and goats is *T. vivax*, next comes *T. congolense*, then mixed *T. vivax* and *T. congolense*, while no *T. brucei* were found in 31,888 animals examined. *T. simae* was found in 5 pigs.

The Maputo region is very important, it has an equable climate, rich pasturage, fertile soil, and the valleys have abundant water for irrigation. It has been reported on by the veterinary officer of the Mission and by Mr Hornby [this *Bulletin*, 1948, v 45, 1068]. The only tsetse flies found are *G. brevipalpis*, near the River Maputo, which feeds chiefly on hippotomus, cattle and small antelopes, and *G. austeni*, near the Libombos to the west where game is abundant. The right bank of the Maputo river is a reserve of elephants of which there are over 2,000, there are also 6,000 head of cattle in this reserve.

and these should be kept separate from the game by a strong sisal hedge. In 1948 the Mission will try the effect on *G. brevipalpis* of applying DDT and gammexane to the cattle. The phenanthridinium compound M & B 1553 was given to 489 head of cattle and a month later hardly any showed *T. congolensis* and all increased in weight. A list of other biting flies and ticks is given.

In the Govuro region near the River Save where there is a high rate of infection, the cattle of the Europeans were treated with dimidium bromide a phenanthridinium compound and in 1948 the Mission will treat all the native cattle with this drug. In Machanga on the left bank of the Save most of the cattle belong to the Africans and are in poor condition and short of grazing areas. In the Chumoso region the Europeans are chiefly interested in cattle for work on their farms in 1945 there were 13 432 cattle all imported from the Tete region they are underfed and overworked and about 80 per cent. suffer from nagana. No tsetse flies have been found in the area but in 1948 a survey with Harris traps and animals as bait will be made. The Munda region is important from its nearness to Beira the plains near the River Pungwe 60 km. from Beira, could support some thousands of cattle. Repeated searches failed to find tsetse flies until Dr Pires found *G. morsitans* in June 1947. Anti-tsetse measures would be relatively easy and cheap. The region is very important for the future development of Beira. The Mossurize area has conditions very favourable for European agriculturists the present African population is too small and the position should be reviewed. It is near the progressive district of Mbezi in Southern Rhodesia. The tsetse situation here is very serious. In the Tete region the periodical bad condition of the cattle is largely due to the shortage of water and pasture owing to over-concentration of the cattle near the permanent rivers. Tsetse flies cannot establish themselves here but occasional contact is possible. The Zôboi region, near Tete and contiguous with Nyasaland, has exceptionally good conditions for agriculture and animal husbandry its average altitude is 900 metres, its climate is agreeable the soil is fertile and water is abundant. This area and the adjoining one of Angónia should supply the neighbouring coal mines of Moatze and future local industries with agricultural products.

The author advises that priority should be given to those regions with the most urgent need or which have the greatest economic importance—Maputo Govuro Munda and Tete.

Tsetse control—Maputo region Hornby studied the breeding ground and resting places of *G. brevipalpis* and began an experiment in control based on clearing. A tractor cleared one hectare (about $\frac{1}{4}$ acres) per hour which is about equal to the work of 200 labourers the cost was 435 80 x/s 10/1 not counting European supervision. The results of searches for flies and pupae during the next half year or more showed that it is possible and economical to control *G. brevipalpis* in Maputo either by settlements protected by peripheral clearings or by discriminative clearing.

Mutuali region, in Niassa province The Centre for the Scientific Investigation of the Cotton-tree needed protection from sleeping sickness for the workers clearing hunting of game traffic control and resettlement (that is sleeping sickness foci were carried out measures which are described in some detail. The results were good and the development of the area should be continued.

The game problem—The Colony has enormous numbers of wild animals including many thousands of elephants and buffaloes which have recently greatly multiplied. The author discusses the question thoroughly. Much damage to farms is done game is a reservoir not only of trypanosome diseases but also of several other fatal diseases of domestic animals but there are strong reasons for preserving it. The interest of the people should be

paramount and game should be killed in regions with agriculture and cattle, but should be protected in reserves and national parks where economic development is not interfered with. A fresh-water fish industry should be developed as a valuable source of protein food.

The Report is an interesting record of much valuable work. The coloured maps are most helpful to the reader. J. F. Corson

GALLIARD. Considerations sur la parasitologie [Reflections on Parasitology.]
Reu. Paludisme et Méd. Trop. 1949, June 15 v. 7, No 61, 154-63

This is an abbreviated account of the lecture that the author gave to the Faculty of Medicine of Paris on his inauguration to the chair occupied for 30 years by his famous predecessor E. Brumpt. It is a review of the modern trends of the subject, coloured by the rather special outlook of the Paris School. He first shows how inaccurate is the idea that morphology has had its day, illustrating this by the example of the importance of minute sub-divisions of anopheline species in malariology, where on a number of occasions these details have provided the final clue to a problem. He is not a rigid systematist, however: e.g. he fully recognizes the importance in medical practice of different strains of the species of plasmodium, filaria and other helminths and is willing to relax the laws of nomenclature in order to define these strains by special names. Much of the lecture was devoted to problems of immunity, the divergent ideas on this subject were shown to be due to various causes: e.g. the existence in different regions of biotypes showing different degrees of adaptation, the rôle of nutrition, etc. Chemotherapy has made immense strides, although it has often had a special difficulty to overcome—namely, the inaccessibility of the parasite to the drug, whether an adult filarial worm or an exo-erythrocytic schizont. In the preventive field, DDT offers immense possibilities, it is stated that after its use in Italy there was not a single death from malaria in 1948, the first year without such a death for 23 centuries.

Throughout his paper wherein the author modestly refrains from any mention of his own not inconsiderable contributions, he emphasizes the importance of the parasitized person rather than the disease itself.

P. C. C. Garnham

REFED, J. G. General Report on the Health of the Estates of the District [Batang Padang, Perak, Malaya] for 1946, 1947 and 1948. 11 mimeographed pp. 1949, Mar. Sungkai, Malaya.

This report on the health of a group of estates in the Batang Padang District of Malaya for the years 1946, 1947 and 1948 is of interest as a glimpse of changing conditions in the health of labour forces. The total population was 9,615, of whom 6,836 were Indians, the vital statistics referring to this last group since the war the births have increased greatly from a previous normal of about 38 per 1,000 to 61.3 in 1947 and 52.4 in 1948. The death rate has shown a steady decline since the war to 5.3 but in the absence of any figures on the age situation of the population this is difficult to interpret. The infant mortality rate has fallen to a low record of 87 per 1,000 live births. In common with the rest of Malaya, malaria has shown a marked steady decrease, the spleen rate in children falling in three years from 35.3 to 4.3 per cent. The explanation for this is not clear, it does not appear to be due to the use of suppressive drugs and the arguments in favour of increased immunity are weak, it would appear to be associated more with changing cultivation practices. On the other hand the nutritional state has not improved and the author considers that the root cause of sub-nutrition is certainly not solely economic as little improvement in the nutritional state accompanies improvement in the economic state. Education in feeding habits seems necessary. Anaemia

is markedly increasing and is becoming one of the most important causes of sickness and inefficiency particularly among women. The report is accompanied by nine tables of statistics.

PÉREZ GARCÍA, R. Comentarios sobre la labor realizada por el Laboratorio Clínico del Distrito La Salina durante el lapso 1938-1947 [Analysis of Ten Years Work at the Clinical Laboratory La Salina, (Venezuela)] *Bol. Med. Caracas*. 1949 Jan., v 1 No. 2, 161-81 1 graph. English summary

This is a condensed account of the work carried out at the clinical laboratory of the Creole Petroleum Corporation's Medical Department at La Salina, Venezuela during the decade 1938-1947. The district concerned lies north-west of Lake Maracaibo. The employees and their families comprise "1474 persons. During the period 24,834 faecal examinations have been made and it is stated that intestinal parasitosis is present in 8 out of every 10. The commonest 37.8 per cent., is *Trichomonas hominis* and next in order *Entamoeba coli* (37 per cent.), *Ascaris lumbricoides* (71.8) *Trichuris trichiura* (18.3) *Chilomastix mesnili* (15.3) *Giardia lamblia* (11.3) *E. histolytica* (4.5) and its cysts (4.3). Of 1,365 schoolchildren examined, 89.4 per cent were harbouring parasites and 36.6 per cent had more than one the commonest being *Ascaris*. Cysts of *E. histolytica* were found in 8 out of 100 cockroaches (*Blattella americana*) examined and in 2 of the same number of flies (*Musca domestica*). Malaria is rife but much less in the last four years, the morbidity per mille in the 5 years 1943-47 being 53.3, 29.9, 14.5, 14.1 and 7.9 respectively. The infection in 86.6 per cent is by *P. vivax*. Typhoid fever is not common, but the number of cases, which in 1944 to 1946 were 6, 5 and 4 respectively rose to 11 in 1947. All the proved cases occurred in parts outside the sanitised sites." Syphilis which had been high, 73.4 per mille in 1943 fell to 43 in 1944 and in each of the next 3 years has been round 17 per mille. Mears of urethral discharge examined for gonococci numbered 4,800 and positive cases have tended to increase during the last 4 years but the examination is limited to direct examination of stained smears.

H. Harold Scott

BOOK REVIEWS

SCHÖNRODER Fritz et al. *Chemotherapy. Flat Review of German Science 1939-1948*. 704 pp. 6 figs. 1948. Published by Office of Military Government for Germany. Field Information Agencies Technical British French U.S.

This account of chemotherapeutic research in Germany during the war years is produced by the FIAT branch (Field Information Agencies Technical) of the Military Government of the British, French and U.S. Occupation Zones in Germany. It is a more polished production than the hastily prepared BIOS (British Intelligence Objectives Sub-Committee) report which served such a useful purpose a few years ago by giving the widest possible publicity to available information on German scientific progress during the war. Unlike the latter production the present one is a printed compact booklet, written not by the interviewing teams who visited Germany immediately after the war but by the German scientists themselves. The senior author is Fritz SCHÖNRODER and there are many other well-known names such as those of DOMAG, HARTH, MÜLLER and M. C. among the 19 contributors.

Although the title page, the foreword (by the Chiefs of the three FIAT services), and the table of contents appear in English, the entire remainder of the volume is in German. It is in the form of 23 self-contained articles, well documented and with useful bibliographies. Where necessary, suitable reference is made to work carried out before the war leading up to particular developments described. There is an adequate author- and subject-index to the volume as a whole. The production is worthy of wider circulation than appears possible as yet, and we learn in the foreword that "The manuscript from which this volume has been derived has been turned over to a committee of German scientists which will make the arrangements necessary for printing other than this strictly limited edition. The latter is transmitted by the respective FIATs to their Government for distribution."

In his introductory note, SCHÖNHÖFER emphasizes the importance of close liaison between chemists and medical men if there is to be any substantial progress in the field of chemotherapy. And yet the element of chance continues to play a big rôle in the emergence of commercially successful preparations. Hardly a dozen such have arisen from the 20,000 compounds examined in 5 to 10 different types of animal test during the past 35 years in the Chemotherapeutic Laboratories of the *I G-Farbenindustrie* at Elberfeld.

The individual contributions are uneven in length and scope, but none is without some interest. The longest is a comprehensive account in 52 pages by PRIGGE of the experimental chemotherapy of tuberculosis and the biochemistry of the bacillus. Tuberculosis is also covered at some length, together with leprosy, in a contribution by WAGNER-JAUREGG. Then there are quite short articles, as for example a paper in 4 pages by KIKUTH on the sulphonamide treatment of virus infections, in which special reference is made to the suitability for laboratory investigations, of the broncho-pneumonia virus of rodents described by GONNERT.

Chemical and biological aspects of the chemotherapy of malaria are covered by 6 chapters in 56 pages. Chemical work in this field in Germany did not go far beyond exploration of quinoline and acridine derivatives, with "Sontochin" and "Endochin" among the quinolines as the best-known products. "Sontochin" was first tested in a limited way already as far back as 1937, and the story has often been told (though not in the volume under review) how a stock of this substance of unknown composition at the time, was captured in North Africa in 1943, and then carefully studied in the U.S.A., where a closely similar compound, "Chloroquine" (which is "Sontochin" minus its 3-methyl group) eventually emerged as the most highly recommended product of the U.S. war-time drive for new antimalarial agents. "Endochin", among the quinolines, is an interesting departure from the classical heterocyclic alkylaminoalkylamine type of synthetic antimalarial. It is said to have given better results than paludrine in sporozoite infections of *P. cathemerium*, though not in those of *P. gallinaceum*, but it proved to be of little or no value in human malaria.

Other chapters deal with quaternary quinoline compounds as agents against trypanosomiasis and babesiasis, 4-aminoquinolines (such as Surfen C for *T. congolense* and 7602 Ac for *T. cruzi* infections), organic bases as amoebicides, metals and metalloids in general, sulphonamides and related compounds as both antimalarial and antibacterial agents, and the xanthone drugs (the "Miracils") for bilharziasis. Interesting short chapters deal with nitrobenzoic acid esters and isomers of N-methyl acridone as antibacterial substances, and with the curious discovery that replacement of the *p* *p'* chlorine atoms of DDT by NO₂ groups converts this substance from an insecticide into a chemotherapeutic agent for experimental typhus infection.

laid down by the Government trypanosomiasis service are given in tables. Atoxyl and pentamidine are used in early cases and Orconine and Tryparsamide in late cases. It should be noted that most of the information in this chapter is only applicable to the infection caused by *T. g. sensu*.

A chapter on ophthalmology includes among many other things a detailed account of an operation for trichiasis. This may suggest that hospital assistants in the Upper Volta are accustomed to perform this operation on their own. A number of coloured drawings of common eye lesions are given. The laboratory section is too short but contains an amount of practical information useful to hospital assistants including diagrams of parasites and bacteria.

A White Sister has contributed an informative section on the care of babies and this is of special value for only too rarely have African hospital assistants any knowledge at all of the care of the young.

Dr. Goarnisson has evidently a vast experience of medical work in West Africa and his book would be of value to a teacher of African hospital assistants or dispensers or dressers in any part of tropical Africa but it is doubtful whether it is of great value to the hospital assistants themselves in its present state. A severe pruning would however render it eminently useful.

1949

[No 11

SUMMARY OF RECENT ABSTRACTS*

IX LEPROSY

General

A bibliography of leprosy from the year 1500 has been published by KEFFER (p 1133) A history of leprosy in Brazil has been written by DE SOUZA-ARAUJO (p 1132) This completes a great task, the first volume of which was published some time ago

A special issue of *Leprosy in India* (p 790) is devoted to the conference held at Wardha This should be read in full

DHARMENDRA (p 791) declares that leprosy legislation in most of India is out of date He outlines some of the points which should be included in future acts In the same discussion COCHRANE (p 791) makes the point that any legislation which encourages an atmosphere of dread, and drives patients into hiding, is bad It is not practicable to isolate all infective patients, and investigation is required to discover the minimum amount of segregation needed to control the disease

Epidemiology

The distribution of leprosy throughout the world is dealt with in a supplement to the *International Journal of Leprosy* (p 436)

The number of cases of leprosy in Norway has diminished from 3,000 in 1856 to 23 in 1943 (HARBITZ, p 607)

Leprosy is prevalent in the Belgian Congo and although the general incidence is probably no more than 5.5 per 1,000 of the population, DUBOIS (p 436) quotes documents to show that in some villages up to 100 per 1,000 are affected The commonest exposure is domestic For control, agricultural colonies have been instituted, largely under the care of medical missionaries, most of the patients in them have lesions of the nerves [This is a long communication which should be studied in the original]

CHAUSSINAND (p 607) has analysed 1,002 cases of leprosy in Cochin China, in relation to age and sex Three-quarters of the patients were males There were many more male than female patients in the age group 15-20, which probably reflects the greater opportunities for infection experienced by males outside their families Up to the age of 15 rather more female than male children were infected, and the female rate rose at ages 25-29 and 40-44, probably reflecting the stresses of child-bearing and the menopause

*The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1948 v 45 References are given under the names of the authors quoted and the pages on which the abstracts are printed

DOUGLASS *et al.* (p. 53) have carried out a detailed enquiry into the histories of 7,204 families in the Philippine Islands in relation to leprosy. The births date back to 1893. They found that infection rates in those born in 1911-23 were only one half of the rates in those born in 1893-1910 and that in families in which lepromatous leprosy had occurred the fall in incidence had been even greater than this. Compulsory segregation was introduced in 1907 and this may have been a factor but other changes also took place particularly a rise in the standard of living.

ATCOCK and GORDON (p. 186) discuss leprosy in veterans of the American forces. Most of those known to have the disease were born in the endemic areas of the United States and many had not served in endemic areas overseas. Leprosy is still endemic in Texas, but many of the patients diagnosed there were born in Mexico (JOHANSEN p. 610). MCCOY (p. 1007) discusses the few cases of leprosy in California, very few of whom were infected in that State.

FLOCH (p. 437) reports on leprosy in French Guiana, where 5.1 per cent. of the population are infected. One half of the new cases discovered are in children under 15 years, and there is a real danger of spread from infected schoolchildren to their schoolmates. Familial infection is evident and a case is quoted where a servant infected five infants. Europeans are usually only infected after long residence but they do not show the same degree of resistance to the disease as is characteristic of the local people.

RISI (p. 438) states that in the humid Amazon valley of Brazil the incidence of leprosy is high—1.0 to 3.8 per 1,000—but in the dry north-east it is 0.9 or less. Proportionately there are more severe lepromatous cases in the north-east than in the more humid areas. BRAGA (pp. 1007-1009) found leprosy in 0.35 per cent. of 69,764 industrial workers in Rio de Janeiro.

TAXIS BOW

CHAUSSINAND (p. 1006) reviews the history of contact in 1,223 patients in Indo-China: the indication is that the disease may be contracted through contact of comparatively short duration. ATCOCK (p. 712) discusses conjugal leprosy, and the rôles of contagion and hereditary susceptibility: the original should be consulted.

FORBETT and OLSEN (p. 441) report two cases in which leprosy was apparently acquired during the process of tattooing.

STOLPER (p. 91) refers once more to his theory that leprosy is transmitted by the bites of cockroaches, and gives details of their anatomy and ecology.

Aetiology

CHAUSSINAND (p. 187) recognizes four morphological forms of *Mycro leprae*: the normal forms, large forms undergoing evolution (not found in lepromata), those undergoing transverse division (in globi and in stages of rapid multiplication), degenerating forms in patients undergoing successful treatment.

The same author (p. 187) sums up the attempts which have been made to cultivate *Mycro leprae*: there may have been some sign of growth in some attempts, but subculture has proved difficult or impossible and most of the workers who have tried to cultivate the organisms have failed or have been misled by apparent increase in growth of the inoculum. On injection *Mycro leprae* killed by heat give negative local reactions in lepromatous leprosy and positive in tuberculous leprosy; similar injections of other acid-fast organisms give positive reactions in tuberculin-positive persons. *Mycro leprae* are phagocytosed slowly after injection into the body cavity of the wax moth but other acid-fast organisms are rapidly fructigenerated. These tests are useful for recognition of *Mycro leprae*. H. (p. 168) sums up his extensive work on inoculation of leprosy material into animals. This has been very disappointing;

since general infections, of a kind which afford opportunities for testing the value of drugs, could not be induced

DE SOUZA-ARAÚJO and ROSSELL (p 344) have isolated acid-fast bacilli from drainage effluents of a leprosarium in Brazil, on cultivation these organisms resembled those previously cultivated by the authors from leprous material

A modification of the carbol-fuchsin method of staining *Mycobacterium leprae*, in the cold, is described by ZANETTI (p 91), who claims better results than by the hot method

In a paper written some years ago STEINIGER (p 1008) summarized the arguments for the now discredited theory that there is some connection between leprosy and the sapotoxins of *Colocasia* CHAUSSINAND (p 1012) has enquired into this question of *Colocasia* in Cochín-China, like most other workers he concludes that it has no significance

Classification

In discussing the modern classification of leprosy into lepromatous, tuberculoid and uncharacteristic forms, IGNACIO CHALA (p 345) makes the point that the last is a transition stage, and that most patients ultimately become either lepromatous (with negative lepromin test) or tuberculoid (with strongly positive lepromin test) PORTUGAL (p 439) has examined a group of patients in relation to the South American classification He agrees that the uncharacteristic cases may evolve into either tuberculoid or lepromatous disease, but they may remain non-characteristic RODRIGUEZ (p 439) proposes the addition of a fourth type to the three recognized by the Pan-American Conference of 1947 (uncharacteristic, lepromatous, tuberculoid), to which he assigns those types showing only interstitial proliferation He adds various subdivisions of these four main types DE SOUZA LIMA *et al* (p 440) discuss the South American classification in relation to the pathology of the various types and stages It is based on clinical immunological and histological features

DUBOIS (p 438) is critical of the classifications proposed recently by South American workers, and suggests one of his own, based on the bacillary content of the tissues, but allowing for clear distinction of lepromatous, tuberculoid and neural cases It is somewhat complicated

Tests

DHARMENDRA (p 612) has contributed a detailed review of the literature on the lepromin test

NOLASCO (p 613) has shown that lepromin keeps its properties for very long periods even when it is not stored in a refrigerator

AZULAY (p 440) thinks that the mechanism of the lepromin reaction is based on the constitutional reactivity of the tissues, and that this may be accelerated by *Mycobacterium leprae* or *Mycobacterium tuberculosis* In children of leprosy patients, SAYAGO (p 91) found no increase in the tuberculin-positive rate over the rate in controls, but there was a high rate for the lepromin test CONTRERAS and JAQUETI (p 1008) have carried out the lepromin test on persons free from leprosy, and found it positive in 44 per cent, especially in those with tuberculous skin lesions, varicose ulcers, and other skin conditions They therefore regard it as useless for diagnosis

IGNACIO and TIONG (p 612) confirm previous work which showed that there is a tendency of young leprosy children to react more strongly to lepromin with increasing age and with repeated tests There seemed to be a direct relationship between repeated testing and clinical improvement, which may indicate some immunizing value The lepromin test is of prognostic value, children showing consistently weak reactions have poor prognosis CHAUSSINAND (p 1009) confirms the value of the intradermal lepromin test in prognosis In healthy

children, however, he found remarkable response and the lesions

Nov. 1949

Reaction with either the tubercle bacillus

" " prury bacillus—or with BCG

A study by DR VOUTA LIMA and DE SOUZA CAMPOS (p. 717) of 800 patients who were tested with lepromin in 1941 and of the progress of the disease in them, showed that although the test has considerable value in prognosis (especially in tuberculoid leprosy) this is by no means absolute.

Recognizing the value of the lepromin test in prognosis, and the fact that a delayed positive test may be given by persons who have not been in contact with leprosy patients, BECHELLI (p. 1010) suggests that all persons who attend on leprosy patients should be tested. Positive reactors should continue at work but should be re-tested at intervals, and if the test becomes negative their work should be changed. It is however rare for healthy attendants to contract the disease.

FERNANDEZ and MENCAU (p. 611) find that when desiccated *Mycobacterium leprae* (from lepromatous tissue) are suspended in oil, and injected intradermally as in the lepromin test the reaction in 48 hours is intense in all forms of leprosy including the lepromatous form. But similar (though less severe) reactions can be provoked by typhoid bacilli in oil. The late reactions are strongly positive in tuberculoid, but negative in lepromatous cases, but the injection itself sometimes produces a temporary sensitization to lepromin.

DR MILSQUITA (p. 616) describes Seabra's photo-oxidative test in leprosy which has apparently some prognostic significance.

OLIVEIRA CASTRO *et al.* (p. 1010) give the results of a flocculation test which is positive in 73 per cent. of lepromatous cases but rarely in tuberculoid leprosy or other diseases.

Clinical Findings

SPENCER (p. 797) describes the clinical features of leprosy.

MAXALANG (p. 611) has found histological changes in the clinically normal skin of leprosy patients and thinks that these may be the sites of future lesions. He holds that infection takes place only in very young children from skin contact, and quotes evidence for this opinion.

DA VEIGA (p. 1091) describes bone and joint lesions of the hand and feet in various forms of leprosy. The process was chiefly destructive—osteoporosis, rarefying osteitis, cyst-like appearances—and may have been due to vascular disturbance. Osteo-articular lesions were most common in patients with nerve lesions. MOYSTERIC and RAGAZIN (p. 313) describe a case of gonorrhea, apparently due not to syphilis, but to leprosy; they discuss the bone lesions of leprosy.

WOLCOTT (p. 613) makes the point that erythema nodosum occurring in leprosy is often confused with the acute lepra reaction and gives certain points of differentiation between the two conditions. WENTZ (p. 1110) quotes evidence which tends to the view that the lepra reaction is often followed by improvement in lepromatous lesions.

OTERMAYER (p. 138) draws attention to the condition described as diffuse lepra, which is a common form of lepromatous leprosy. It is chronic and which is usually fatal in about eight years. It develops slowly and in a more protracted form for some time but it is highly infective. Cutaneous nodules are absent but there is diffuse infiltration of the skin of the whole body and peculiar lepra reaction in which tender erythematous and infiltrated small nodules appear which become necrotic and leave small sharply-defined scars. The Mitsuda reaction is persistently negative indicating lack of resistance.

by two weeks rest when ferrous sulphate was given. Such courses were repeated. Clinical improvement was great in some (but not all) cases, though bacteriological improvement was not so great. DHARMENDRA and CRATTERJEE (p. 78) describe their experience with diarsone and sulphone in lepromatous leprosy. The clinical results were good but bacteriological improvement was not marked. There was no effect on nerve pains and nerve abscesses but leprosy ulcers healed and eye conditions improved. It is necessary to keep a constant check on the blood by simple haemoglobin estimation and if this is done the treatment is safe. For most cases, however, hydrosulphates remain the best drugs for routine use.

FISCH *et al.* (p. 1011) observed improvement in about two-thirds of patients with lepromatous disease within one year of the start of treatment with promin. The best results were obtained in patients receiving the higher doses (2-3 gm. or more each day). The authors advocate the simultaneous use of chaulmoogra.

Promin is rather less toxic than the other sulphones but JOHANSSON and ERICKSON (p. 613) state that it has no other advantages and that they do not propose to continue its use.

SCHULMAN and CASTIGLIA DI CROCE (p. 1011) examined skin biopsy specimens in lepromatous patients before and after treatment with chaulmoogra or promin. The improvement was very marked with both drugs.

RODRIGUES (p. 814) states that chaulmoogra destroys leprosy bacilli in large numbers and leads to improvement in the lesion but there is risk of precipitation of surviving organisms by the blood. It is wise to give treatment with the sulphones for several weeks before pushing chaulmoogra to the point of clearing of the lesions and dispersal of the organisms so that they may be bactericidal drug in the blood stream. SCHULMAN (p. 441) writes critically of the effect of chaulmoogra in lepromatous leprosy but makes the point that this treatment must be given regularly and in doses of the maximum amount that can be tolerated in the minimum time. When this was done 40 per cent of lepromatous patients were rendered clinically and bacteriologically better and 40 per cent were definitely improved. He supports this view (p. 411) by quoting a group of patients who did not improve on 30-50 c. monthly but who did so on an intensive course of 100-150 c. monthly (see also p. 713).

He writes favourably of iodized hydrosulphates if compared with the ordinary (or iodine) in lepromatous leprosy. From Brazil howe (p. 211) and (p. 714) report most unfavourably on chaulmoogra but has obtained excellent results with promin and diarsone.

FISCH and ERICKSON (p. 447) have tried streptomycin in leprosy but although improvement was noted, it was no greater than that achieved with the sulphones which are less toxic. However it is too early to judge the value of streptomycin. FISCH *et al.* (p. 447) used it for local application for leprosy ulcers and report satisfactory results.

Dr SORELLA ARAUJO (p. 346) has found that streptomycin has some inhibitory action *in vitro* on acid-fast organisms isolated from leprosy patients but it had no curative action when injected into the patient.

FELIX DEZ and BERGER (pp. 911-1013) report favourably on formaldehyde sulphonylate of sodium given intra-arterially or intramuscularly in lepromatous leprosy. It is a reducing agent and they used it for this reason but there are no sure that it is why it produces its effect.

Although antimony is not specific for leprosy, DE VRIES (p. 14) has found it very useful in the lepra reaction and in the bone and bone marrow associated with other drugs.

In a few cases, administration of the anti-histamine drug benadryl gave some benefit during the allergic lepra reaction, Box (p 713) thinks that further trial is indicated

Good result in the treatment of the leprous reaction is claimed by FERNÁNDEZ *et al* (p 1012) who used transfusion of the blood of patients convalescing from that reaction

PICCARDI and RADAELI (p 1092) have investigated the effect of molybdenum and methylene blue on leprous nodules The original abstract gives details

Control

ROTBERG (p 1013) thinks that the fundamental basis of prevention is isolation and treatment of the infective patients Others, for instance those with tuberculoid leprosy, can remain at home if nasal smears are negative Contacts should be tested with lepromin, those who are negative should be examined each week

MACDONALD (p 1014) has written an account of the agricultural leprosy colony at Itu in S Nigeria, and the extensive rehabilitation work accomplished there

Charles Wilcocks

MALARIA

BRUMPT, L C Paludisme autochtone ou paludisme accidentel Contribution à la 'pathologie par la seringue' [Malaria, Indigenous or Accidental Contribution to "Syringe Pathology"] *Bull et Mém Soc Méd Hôpit de Paris* 1949, Nos 9/10, 392-7

The natural transmission of *P falciparum* in northern countries is such an exceptional event that the occurrence of such an infection in a patient who could not have acquired it naturally elsewhere demands a careful inquiry into the possibility of the infection having been injected accidentally, intravenously or otherwise, during the course of some therapeutic procedure Among the cases of indigenous *P falciparum* reported in France six only appear to the author to have been authentic Most of the other infections have been acquired accidentally during the intravenous injection of novarsenobenzol It is pointed out that mycotherapy may be the cause of such infection, neither penicillin nor streptomycin are schizonticides

Norman White

BINCER W Malariological Problems in Poland *Bull Inst Marine & Trop Med, Méd Acad Gdansk, Poland* 1948, v 1, No 1, 59-63, 2 maps

Because of damage distress and large-scale migrations of populations, the disasters of war have always contributed to fluctuations in the incidence of communicable diseases This disturbance of biological balance has been all too clearly illustrated in Central Europe of recent years and has resulted, among other things in increased intensity and diffusion of malaria or in its appearance where it has previously been absent or latent Such events have already been noted in the case of Czechoslovakia [this *Bulletin* 1948 v 45 480] and the author now records the situation in Poland up to 1948

Polish refugees have been repatriated from a very large number of malarious countries and now represent a considerable number of the population Alteration of frontiers has involved inclusion of highly malarious regions on the Baltic coast and the consequent transfer of potential carriers the geographical state of Poland in 1939 and 1946 shown in two maps illustrates this

Inadequate drainage of fields and marshes, destruction of equipment, lack of men and materials, bombing of water piping and an increase in stagnant pools have all led to increased breeding of anophelines, ruined houses harbour adult mosquitoes in large numbers and the vast loss of cattle has destroyed an important screen against malaria in man. Scarcity of drugs and insufficient hospital beds for patients with malaria (particularly in 1945 when so many beds were filled with patients having typhus or typhoid) added to the difficulties.

The measures to meet this situation are discussed. The financial position of the country is still too restricted to allow of adequate large-scale control of mosquito breeding, although much has already been done to reclaim marshes on the Baltic coast. Cattle re-population started by UNRRA will take many years to be effective. Drugs have been supplied on a considerable scale in the form of atabrine, mepracrine and plasmoquine chiefly from the American Red Cross and of 200,000 tablets of proguanil (paludrine) from the WHO. Hospital beds are now available for malaria patients.

Routine malaria surveys are necessary and it is stated that large-scale anti-mosquito measures should be started not later than March. The malaria season begins in April, incidence increases to a peak in July-August, decreases slightly in September and then falls rapidly. Unless very vigorous methods are enforced an increase over the 1947 morbidity is expected.

The principal vector in Poland is *Anopheles marshalli* meunier. The infection is that of *P. vivax* but a new problem has arisen with the influx of repatriates from U.S.S.R., Palestine and East Africa with rising *P. falciparum* infections among them. It seems unlikely that the local vector or general conditions will allow any major propagation of *falciparum* infection in Poland, but potential carriers should be closely watched, particularly in malarious areas. "The nature of the parasite should be stated in all malaria cases around such a vector." Constant vigilance such as this on the part of the Public Health authorities is possible in properly organized anti-malaria centres but microscopes, slides and staff are not always available.

Should the indicated measures fail (or not be undertaken) (1) malaria would develop in Poland to a problem of grave concern to the nation.

H. J. O'D. Burke-Gaffney

TORANZOS, L. B. Casos de paludismo en el Dep. de Mercedes (Provincia de Corrientes). Cases of Malaria in the Department of Mercedes, Corrientes Province.] *Rev. Inst. Bacteriol.* Dr. Carlos G. Malbrán. Buenos Aires, 1941. Sept. 10. No. 2, 196-7.

The Province of Corrientes, with Brazil, Paraguay and Misiones on its borders, all malarious regions, would naturally be expected to suffer from the same infection, especially with the people's resistance lowered by the great prevalence of hookworm. Nevertheless there is little documentary evidence of malaria in Corrientes. It is known that men and women come from outside to work in the rice-fields for example and that they may be arriving malaria. The author therefore thinks it important to call attention to four cases, three of which would appear to have been autochthonous. Two came from Mercedes Department and one from the neighbourhood of plantations on the Corrientes River. One was a woman, 149 years from Mercedes and suffered from chills and heavy sweat and periodic attack of fever but no enlargement of liver or spleen. She suffered from double benign tertian malaria. The second was a child of 3 years brought to the rice-fields in the Corrientes River. He also had a *P. vivax* infection. The third was a woman of 40 years

with "*Tertiana duplex*", and with enlarged liver and spleen. The fourth was a man of 40 who had come from Chaco. His blood showed numerous benign tertian parasites. Mercedes lies at the centre of Corrientes Province and the author has found larvae and adults of *Anopheles*, he is at present studying the species

MACKERRAS, M. J. & LEMERLE, T. H. Laboratory Breeding of *Anopheles punctulatus punctulatus*, Döhlitz Bull. Entom. Res. 1949, May, v, 40, Pt 1, 27-41, 7 figs [11 refs.]

A daily supply of large numbers of young female mosquitoes was required during the wartime investigation into the chemotherapy of experimentally transmitted malaria which was conducted at Cairns, North Queensland, Australia. Other sources having proved inadequate a laboratory colony of *Anopheles punctulatus punctulatus* was eventually established. In this paper the authors describe the equipment which they used and the daily routine which they followed, and also record their observations on the life-cycle and behaviour of this anopheline.

The insectary was 22 feet long, 8 feet wide and 8 feet high. Its eight windows were kept open in summer but were closed in winter when artificial heat was used to maintain the temperature inside the insectary at about 27°C. Direct sunlight never reached the cages in which the adult mosquitoes were kept, but was allowed to fall on the dishes of larvae for part of the day. There were four cages, each 3 feet high and 2 feet square, they had two removable glass sides and two fixed sides of wood, a removable wooden roof and a fixed wooden floor. A strip of moist blanket inside the cages provided damp dry time resting places and maintained a high humidity. Sheets of fresh apple were supplied each night and a blood meal was offered, better results were obtained when the female mosquito fed on a human arm than on an animal. Each cage could accommodate 2 000 adults.

Eggs were laid 72 hours after the first blood meal and 48 hours after subsequent meals. The batches of eggs were kept separate so that the exact age was known. Some eggs hatched after a period of desiccation lasting 5½ days. Early batches consisted of 30 to 100 eggs, but later ones contained 200 to 250. Normally eggs hatched in 42 hours. Favourable conditions for larvae were shallow water, food given in small quantities at frequent intervals rather than in large amounts at one time (the food was a proprietary baby food powder), avoidance of overfeeding and overcrowding, a substrate of mud at first and later of sand, and a water temperature of between 32° and 35°C for at least part of the day. The larval stage lasted from 5 to 8 days. The pupae were always washed in a stream of water when they were being transferred to the pupa dishes. A density of 1,000 pupae per 7 square inches of water surface was found to be ideal. The first pupae to be formed were returned to the breeding cages because they contained a large proportion of male mosquitoes, the later pupae were put into other, special cages where the emerging females were kept awaiting infection. The pupal stage occupied 30 to 40 hours and the emergence rate was between 95 and 100 per cent. Adults usually emerged in the evenings and the females took their first blood meal two days later. They spent the day resting and became active after dusk. Mating and egg-laying took place in flight, when laying her eggs the female hovered about six inches above the water, so that the eggs were scattered and not arranged in groups, a reminder that in nature the breeding places are open pools unobstructed by vegetation. The life-cycle therefore from egg to egg took 13 days.

McARTHUR J. The Anophelids of Tambunan, North Borneo. *Bull. Fauna Res.* 1949 May v 40 Pt 1 53-63.

Anopheline surveys made in Tambunan North Borneo during 1939 to 1942 resulted in the finding of nearly 48,000 larvae of 17 species and varieties of *Anopheles*. Four species formed 89 per cent. of the collection, namely *A. lateralis*, *A. kochi*, *A. maculipes* and *A. philippinensis*. More than 1,000 adults of eight species were captured by various methods, including house searching which yielded only 10 specimens, human bait trapping (172), trapping by native assistants (716), jungle searching (1,628) and animal bait trapping (10,013). In jungle searching *A. philippinensis* provided 1,147 specimens and *A. kochi* 447; the animal bait traps yielded 4,454 *A. philippinensis* and 4,541 *A. kochi* while searches by local people in their defective mosquito nets gave a total of 574 specimens of *A. lateralis*.

A. lateralis was ultimately proved to be the only vector of malaria in the locality. It breeds in swamps in dense jungle shade in the presence of dead leaves. It prefers human rather than animal blood and feeds late at night or early in the morning and departs before daylight.

All the other anophelines in this area are regarded as unimportant as a result of dissections or precipitin tests, or observations on feeding habits or because of their scarcity. In addition to those already mentioned the author includes notes on *A. kerrii*, *A. tessellatus*, *A. barbutator* and *A. latipes* (one female and no larvae) and *A. aethiops* (larvae only of the typical form and three varieties). H. S. LECHE

REID J. A. A Preliminary Account of the Forms of *Anopheles lateralis* Dyar (Diptera: Culicidae). *Proc. Roy. Entom. Soc. of London*, Ser. B, 1949 Apr 15 18 Pt. 3 4 47-53 - figs. 123 etc.

It is now known that *Anopheles lateralis* is an efficient vector of malaria in Assam, Borneo and Burma. The systematics of this species are disturbed and at least 3 varieties are recognized four of which occur in Malaya. These varieties are described and a key is given to the identification of the females. H. S. LECHE

FROHNE W. C. & HART J. W. Overwintering of *Anopheles crucians* Wied. in South Carolina. *J. National Malaria Soc.* 1944 June v 8 No. 2 171-3 2 graphs.

In the vicinity of Manning, South Carolina *Anopheles crucians* survives the winter wholly in the aquatic stages and undergoes retarded larval development. In contrast hibernation by the unemerged female is typical for local *A. quadrimaculatus* while *A. punctipennis* is here breed actively all winter.

MEIX, W. Bluttransfusion und Malaria (Blood Transfusion and Malaria). *Munch. med. Woch.* 1941 July 14 81 No. 28 349-5 - 18 col. A general review and discussion.

BOVEXTER A. Ueber die Gefahr der Malariaübertragung durch Blutkonserven. (The Danger of Transmission of Malaria Infection by Preserved Blood.) *Woch. R.* 1949 May 20 44 No. 20 641-5.

Until the last war it was customary, before carrying out blood-transfusion, to ensure that congenital diseases such as tuberculosis and syphilis were

excluded. Then, when men returned from the tropics reports of inoculated malaria in the tropics began to increase and next came the fear of similar occurrences in non-tropical countries in certain cases where blood was taken from those who had come back from the tropics. Blood kept for three days was then thought to be safe, but this was soon proved wrong and, first, eight days and then three weeks were the periods recommended. Instances have, however, been recorded in which the blood of subjects who have not for many years lived in the tropics and have had no attacks of malaria for long periods has transferred infection. In order to avoid all risk the blood of the donor should be examined, says the author, in thick drop for parasites and by the Henry reaction. [The author in his experimental work has shown that *P. vivax* might remain viable and transmissible in blood kept for 13 days and *P. falciparum* for 21 days. See this *Bulletin*, 1949, v 46, 799.]

H Harold Scott

STRANSKY E On Pernicious Attacks of Malaria in Childhood *J Trop Med & Hyg* 1949, July, v 52, No 7, 140-44

A description is given of three fatal cases of malignant tertian malaria in children in the Philippines.

Case I A Filipino girl aged 12, coming from a region where malaria is endemic. One week before admission to hospital the patient developed a low-grade fever which became intensified. Moderate but continuous headache, pains in the chest and vomiting were present. On admission the child looked weak, pale and jaundiced. Owing to abdominal tenderness the liver and spleen could not be palpated, there were no nervous symptoms but haemorrhages and petechial spots were present, especially on the eyelids, face and arms.

A microcytic anaemia was present (colour index 0.57), a leucocytosis of 39 800 per cmm, marked anisocytosis poikilocytosis polychromatophilia, microcytosis, hypochromia and numerous target cells were found. Many ring forms and some schizonts, merozoites and crescent forms of *Plasmodium falciparum* were present in blood smears. The findings suggested an acute haemolytic anaemia. Aralen [chloroquine] by mouth was given, but the patient died 36 hours after admission.

Autopsy showed the liver to be slightly enlarged and slate-coloured and the spleen twice the normal size and slate-coloured, petechial haemorrhages were found in the cortex and medulla of the kidneys, while numerous malaria parasites were seen in smears of the brain, spleen, liver and kidneys, together with degenerative changes in the liver cells. This was a case of extremely severe infection with *Plasmodium falciparum* of long standing, with an acute exacerbation and severe anaemia.

Case II A Filipino girl aged 4 years and 9 months, who, for the 7 months before admission had lived in an area where malaria is endemic. The chief complaints were fever, cough, headache, abdominal pain and loss of appetite, and 24 hours before admission oedema of the legs developed. On admission, the child was strikingly pale but not jaundiced. *Ascaris* ova were numerous in the faeces and blood examination showed marked anisocytosis, poikilocytosis polychromatophilia microcytosis and hypochromia. Nearly every red cell contained malaria parasites—rings, a few schizonts and crescents of *P. falciparum* while most of the monocytes and many granulocytes showed pigment. The patient died suddenly the day after admission the temperature did not rise above 101°F. Owing to collapsed veins quinine had to be given intramuscularly. At autopsy the most important findings were slate-coloured grey matter in the brain with prominent blood vessels and pin-point haemorrhages massive deposition of malarial pigment in spleen, kidneys, liver and brain while numerous malaria parasites were found in the above organs.

Case III. A boy aged 3 years was admitted to hospital with complaint of anaemia infrequent micturition and high-coloured urine. The patient had been ill for a fortnight previously and also came from a region where malaria was endemic and on admission was pale jaundiced, with a temperature of 101°F and pulse of 160. The spleen but not the liver was palpable. Marked anisocytosis poikilocytosis polychromatophilia, microcytosis and hypochromia were present together with numerous target cells and nucleated red blood cells. A few ring and crescent forms " (presumably of *P. falciparum*) were found in the peripheral blood. The child died the day after admission the clinical diagnosis before blood examination was that of acute haemolytic anaemia.

At autopsy the spleen was found to be enlarged to twice the normal size the brain, except for some congestion and oedema without any malarial pigment was normal and histological examination showed no characteristic findings of cerebral malaria.

Death was " sudden and unexpected " in these three cases and two patients showed signs of cerebral malaria and acute haemolytic anaemia. Pernicious attacks of malaria may develop in childhood without characteristic symptoms, [So they can in adults. In the reviewer's experience this type of case is almost invariably fatal. The chief interest in this paper lies in the very full laboratory and post-mortem examinations.] C. F. Shelton

v HALLER, E. Die Erkrankungsdauer der Malaria (insbesondere der Malaria tertiana). [The Duration of Malaria Infection, especially Benign Tertian.] *Ztschr. f. Hyg. u. Infektionskr.* 1948 Aug 17 v 128 No. 34 770-87 1 fig. (5 refs.)

The author defines duration of infection as the period between the last time of infection and the cessation of the last symptom. He quotes from the literature the times which previous authorities have stated these have ranged between wide limits, from 18 months to 8 years. He next states his own experience of 1,262 soldiers in the Adriatic region and Sardinia none of whom showed any symptoms 18 months after infection with *P. vivax*. He quotes Boyd and others that in inoculated malaria relapses if they occur more than two months later indicate inefficient treatment.

In subtertian infection if the patient remains free from fever for eight weeks and parasites are not seen in a thick drop specimen of the blood, the infection can be regarded as cured and in unfavourable cases the infection he states has died out within a year. The quartan parasite is much more resistant and can remain active in the body for more than 10 years. In view of the varied statements of well-known authorities readers will require more than the mere *ipse dixit* of the author that his findings are of universal application. See also this Bulletin 1948 v 45 970. H. H. Read Scott

COOPER, W. C., RICH, D. S., COATNEY, G. R., JOHNSON, F. & YING, M. D. Studies in Human Malaria. VIII. The Protective and Therapeutic Action of Quinacrine against St. Elizabeth Strain Vivax Malaria. *Amer. J. Hyg.* 1949 Jan. 49 No 1 25-40 8 fig. 22 refs.

During the testing of antimalarial drugs in prisoner volunteers at Atlanta the maximum effects to be expected from quinacrine in protecting against the prevention or cure of the St. Elizabeth strain of *P. vivax* were determined so as to provide an adequate basis for comparison with new drugs which were being tested at near toxic doses.

White male volunteers were each bitten by 10-14 *quadrinaculatus* infected with the St. Elizabeth strain of *P. vivax*. Each mosquito after it had bitten three

volunteers in turn was dissected to determine sporozoite densities. Volunteers were kept under close supervision for 18 months, infections with this strain of *P. vivax* usually exhibit a short early period of activity soon after infection, and a prolonged late period beginning 6 to 12 months after infection.

Quinacrine was given as the hydrochloride, U.S.P., in tablets, each containing 0.1 gm of the salt. Dosages are expressed in terms of the salt. Five men were given quinacrine for four days before, on the day of, and for six days after the day of infection. The dosage was 0.8 gm (0.2 every 6 hours) on the first day, then 0.4 gm on each of the succeeding 10 days—4.8 gm in all. Quinacrine plasma levels approached equilibrium at about 30 microgrammes per litre, about the fourth day after exposure. They did not fall below 10 microgrammes per litre till more than 4 weeks after exposure. These five men had their primary attacks of malaria 242 to 350 days after mosquito bites. Four of five untreated controls simultaneously infected had their primary attacks 13 to 16 days after exposure; the other control had a late primary attack. The delayed activity in the patients protected by quinacrine was characterized by one to three late attacks per patient.

Another group of five volunteers was similarly treated but the administration of 0.4 gm quinacrine was continued for 20 days after exposure. Each man received in all 10.4 gm in 25 days. Mean plasma concentrations of quinacrine from day 0 to day 21 ranged from 102 to 148 microgrammes per litre, and did not fall below 10 microgrammes until more than nine weeks after exposure. These five men had primary attacks from 278 to 323 days after exposure; five untreated controls had their primary attacks 13 to 14 days after exposure.

Quinacrine was used therapeutically in 55 acute attacks of this strain of *P. vivax*. Nineteen patients were treated during early attacks, i.e. those beginning during the first 60 days after infection. Dosage varied in these cases. In no case was there further early activity of the infection, but in 18 of the 19 patients late relapses occurred from 178 to 364 days after the last dose of drug.

Twenty-five late attacks occurring six months or more after exposure were treated with 2.8 gm quinacrine in six days, 0.2 gm every six hours on the first day, 0.1 gm every six hours for the next five days. Treatment was begun on or before the fifth day of patent parasitaemia. Five of eight first late attacks, five of eleven second late attacks and none of six third late attacks were followed by relapse at intervals of from 30 to 66 days from end of treatment. In every case where the last day of treatment was on or before day 305 the patient subsequently relapsed. No case where treatment ended after day 351 showed further evidence of infection.

Three late attacks were treated with larger doses of quinacrine 5.2 gm in 12 days. Each of the three had one additional relapse 39, 42, and 43 days after the last dose of drug.

Five patients who were given suppressive quinacrine 0.1 gm daily from the end of treatment of their late primary attacks through the 14th month after exposure to infection exhibited no further evidence of infection.

No serious toxic effects were encountered during these experiments and no course of therapy had to be modified. There were three instances of nausea, two of vomiting and three of diarrhoea.

RUHE, D. S., COOPER, W. C., COATNEY, G. R., JOSEPHSON, E. S. & YOUNG, M. D. Studies in Human Malaria. IX. The Protective and Therapeutic Action of SN 6911 (Sontochnin) against St. Elizabeth Strain Vivax Malaria. *Amer J Hyg* 1949, Jan., v. 49, No. 1, 41-8, 5 figs [11 refs].

The procedure in carrying out these experiments in prisoner volunteers has been described in the authors' paper dealing with quinacrine [above].

SN6911 (Sontochin) was given as the bisulphate monohydrate in tablet form, each tablet containing 0.1 gm. of base. Dosages are expressed in the terms of the base.

Five volunteers were given SN6911 four days before infection on the day of infection and on each of the six following days, 0.8 gm. on the first day and 0.4 gm. on each of the following ten days—4.8 gm. in all. They did not develop patent malaria until 277 to 332 days after infection. Four of five untreated controls had early primary attack 13 to 16 days after infection. The drug was well tolerated, but three of the men had some abdominal distress.

Five volunteers were similarly treated but the medication was continued for 20 days after exposure to infection. They all developed primary attacks 223 to 297 days after infection. Five untreated controls all developed primary attacks 13 to 14 days after infection. All five treated men had gastro-intestinal symptoms: four had anxiety symptoms, insomnia, headache and irritability; all developed a fine tremor of the hands.

Five control subjects were treated with SN6911 during their initial attack. 2.8 gm. in six days—0.8 gm. on the first day, 0.4 gm. on each of the remaining four days. Fever disappeared in two to three days; parasites in from three to four days. All five patients had late relapses 203 to 256 days after the end of treatment.

Four late primary attacks 9.5 to 10.5 months after exposure were similarly treated. Further activity developed in three of these patients 37 to 48 days after the end of treatment. There were no toxic manifestations during the therapeutic trials that might not have been caused by malaria.

SN6911 was not causally prophylactic or curative though it was effective in suppressing and interrupting malaria attacks caused by the St. Elizabeth strain of *P. maei*.
Vernon White

COTNEY G. R., RINE D. S., COOPER W. C., JAMESON E. S. & YOUNG M. D.
Studies in Human Malaria. X. The Protective and Therapeutic Action of Chloroquine (SN 7618) against St. Elizabeth Strain Vivax Malaria. *Proc. J. Hyg.* 1949 Jan. 49 No. 1 49-59 7 figs. 13 refs.

The procedure adopted in these experiments was described in the other paper dealing with pamaquine above. Chloroquine diphosphate was given in capsules or tablets each containing 0.1 gm. of base. Dosages are expressed in terms of the base. Each of five volunteers was given chloroquine on four days before infection with the St. Elizabeth strain of *P. maei* on the day of infection, and on the six following days—0.8 gm. on the first day, 0.4 gm. on each of the succeeding ten days—4.8 gm. in all. They all developed primary attacks of malaria between 254 and 308 days after exposure to infection. Five controls developed malaria 13 to 15 days after exposure. In the treated men detectable concentrations of chloroquine above 10 microgrammes per litre were still present in the plasma 60 days after exposure. The high doses were well tolerated: one subject complained of blurring of vision, nausea and diarrhoea, and another of mild epigastric distress during the first three days of medication.

Five volunteers were treated by a regimen that the medication continued for 20 days after infection. Because of high plasma concentrations (1.5 to 1.894 microgrammes per litre) doses were reduced during the last 5 days of therapy. The total amount given were from 8.7 to 8.4 gm. in 23 days. They all developed primary attacks from 254 to 289 days after exposure to infection. The five control developed patent malaria 13 to 15 days after exposure. All five treated subjects complained of blurring of vision or blurring of

vision which cleared, however, either during or soon after the period of drug administration. Weights, red and white blood cell counts and urine analyses remained normal throughout.

Chloroquine was used in the treatment of 12 early and 11 late attacks of St Elizabeth strain *P vivax* malaria. The early attacks were in controls or in subjects who had received inadequate suppressive medication. The late attacks were relapses beginning later than six months after exposure. Treatment was begun on the fifth day of patent parasitaemia, 0.8 gm on the first day followed by 0.4 gm a day from 1.5 to 5 days. Clearance of parasites and subsidence of fever was rapid in all the early attacks but relapse invariably occurred 164 to 293 days after the end of treatment. Relapses occurred after the treatment of four of seven first late attacks and one of four second late attacks, parasites becoming patent 53 to 85 days after the end of treatment. In the total 23 attacks treated, parasites were cleared from the blood in from one to four days, mean 2.3 days, and fever was terminated in one to two days, mean 1.2 days.

In spite of great activity against erythrocytic parasites chloroquine was neither prophylactic nor curative against the St Elizabeth strain of *P vivax*.
Norman White

COOPER, W C, RUHE, D S, COATNEY, G R, JOSEPHSON, E S, YOUNG, M D & BURGESS, R W. Studies in Human Malaria. XI. The Protective and Therapeutic Action of SN 6771 against St Elizabeth Strain Vivax Malaria. *Amer J Hyg* 1949, Jan, v 49, No 1, 60-66, 5 figs.

SN6771 is 6.6'-diallyl- α , α' -bis (diethylamino)-4,4'-bi-o-cresol. Its value in the suppression and treatment of infections with the St Elizabeth strain of *P vivax* was tested in the manner described above. SN6771 dihydrochloride, 3.0 gm of base a day, was given to five volunteers for four days before infection, on the day of infection, and for six days after infection. Two men developed early primary attacks on the 16th day, two showed early transient parasitaemia but did not develop typical primary attacks till 282 and 291 days after exposure to infection. The remaining subject showed no sign of malaria till 285 days after exposure. Five controls had early primary attacks 13 to 15 days after infection.

In five other volunteers the administration of SN6771 was continued for 20 days after exposure. Their primary attacks were delayed until 258 to 304 days after infection. Each man then had one or two malaria attacks. The 25-day courses were well tolerated, two subjects complained of nausea.

Nineteen late attacks of malaria were treated with SN6771 2.0 gm a day for six days. Parasitaemia and fever were abolished in all cases but the process was slow—two to ten days (mean 5.3) for the clearance of parasites and five days for the removal of fever. Infections became repatent 10 to 16 days after treatment. Relapses occurred after each of the eight first late attacks and after four of seven second late attacks.

DE MELLO, J P. Fifty Years of War against Malaria. *East African Med J* 1949, June v 26 No 6 155-7.

A brief historical review.

CAMBURNAC, F J C. Modernos processos de combate ao sezonismo. [Modern Antimalaria Measures.] *An Inst Med Trop* Lisbon 1948, Dec, v 5, 321-39. English summary (6 lines).

A review and a discussion.

of these sites after 47 and 89 hour respectively disclosed a few schizonts some of which appeared to be in Kupffer cells. It is not stated where the remainder appeared to be.

A second biopsy over the 47-hour site taken 9 days and 18 hour after inoculation and the day after detectable parasitaemia, revealed numerous parasites in the liver sinusoid in a circumscribed area. These parasites were schizont segments or merozoites the latter being free in the lumen. These parasites were often associated with the Kupffer and littoral cell. An obvious comment on this statement is that surely this would be fortuitous once the parasites were in the sinusoid and SHERRY & GARNHAM have described and figured the release of merozoites into the sinusoid.

It is also stated that "other parasites were found in c II which could not be identified these may have been hepatic cells."

On the same animal a splenic biopsy was performed 11 days and 18 hour after inoculation. It is stated that "large bodies resembling schizont and segments were observed in the sinus lumen, the pulp rim and the trabecular rim. Despite this resemblance the nodularity of these forms & white thrombi raises a serious question as to whether they were oocystozoic tags. It is further stated that the cellular reaction within and surrounding these structures resembled the reaction associated with segmenting exo-erythrocytic tags. It is mentioned earlier in this paper that this term hardly a valid comparison seeing that previous oocysts resided in the liver and not in the spleen.

In experiment 3 the liver of a monkey was inoculated at site with 24 and 27 heads infected with gland respectively. Liver biopsies were performed after 81 and 144 hour but only the 81-hour site could be taken microscopically.

Schizont and pre-segments the difference between these is not known. I was found and these varied in size between 15 and 35 μ in diameter. The development of a form of 35 μ in diameter from a parasite smaller than four days is difficult to comprehend. The parasites were found in Kupffer cells but some were in hepatic cells. It is stated that the reaction in the inoculation site was composed chiefly of degenerating liver cells mononuclear cells heterophilic eosinophil and large nests of mononuclear phagocytes all typical of an acute inflammatory host response.

In experiment 4 the monkey was given an intra-venous inoculation of the ground thoraces of 223 heads infected mosquitoes and 2 sacrificed 5 days and 19 hour later. Liver and spleen biopsies were made at 44 and 87 hours after inoculation. Air-dried (crushed) smears of the liver at the post mortem showed five oocystozoic parasites with nuclei arranged in number from 5 to 29. It was not possible to determine the type of the host cell. Considering the fact that the post mortem was performed nearly a day after inoculation, the small number of nuclei difficult to account for and no explanation is given.

In the specimen obtained at the biopsy made at 44 hours small parasites resembling the metacryptozoites of a human malaria were found in the Kupffer cells and this is suggested as indicating the possibility that type one segmental occurs about the 40th to 48th hour after infection. A further statement is made that in none of the histological preparation of the parasites show large vacuoles.

A series of control experiments with normal uninfected mosquitoes was carried out with negative result.

A short discussion compares the morphological characters of the pre-erythrocytic tags of *Plasmodium* with those of human malaria parasites of *Plasmodium falciparum*, *Plasmodium vivax* and *Plasmodium malariae*.

[In considering the details of the experiments it is felt that certain points in the description are left somewhat vague. It is not made clear what is meant by the term "biopsy", i.e., whether it refers to a specimen removed by splenic or liver puncture or a specimen of spleen or liver tissue removed by open operation. Again, where inoculations were made into liver directly, it is not stated whether the liver was first exposed by operation in order to make more accurate the location of the respective inoculations.]

Another point to be noted is that it is at least open to question whether results obtained by the crude process of direct inoculation of mosquito tissues into the liver, with the consequent damage to the tissues and the subsequent reaction of the latter, represent conditions in which the data can be fairly compared with those obtained under the more normal conditions which follow the bites of infected mosquitoes.

The paper would appear to bring out some major points of difference when the findings are compared with those obtained in previous work. Thus the impression gained from it is that the author emphasizes that the location of the exo-erythrocytic stages is in cells of the reticulo-endothelial system, in both liver and spleen, rather than in the hepatic cells. Another fundamental point of difference is that in experiment 3, the occurrence is reported of schizonts as large as 38μ only 94 hours after inoculation. This is the more remarkable if, as the author suggests, there is an earlier cryptozoic stage which matures at 40 to 48 hours after inoculation, as the implication would then be that the parasite had grown to a size of 38μ in about 48 hours.

Beyond these remarks further comment would not be justifiable without examination of the actual preparations illustrating the conclusions drawn in the paper.]

H E Shortt

MANWELL, R D & FEIGELSON, P. *Glycolysis in Plasmodium gallinaceum*. *Proc Soc Exper Biol & Med* 1949, Apr, v 70, No 4, 578-82, 3 figs

The authors adapted, with limited success, the technique of BALL and colleagues [this *Bulletin*, 1945, v 42, 867], to the culture of erythrocytic forms of *P. gallinaceum* and made a detailed study of the glucose requirements of the parasite. The strain was maintained by inoculation of 3-week-old chickens with brain suspensions or parasitized blood by the intramuscular or intraperitoneal routes. Blood was collected from the chicken heart, in presence of heparin, during the rise of infection and used in the rocking apparatus of BALL *et al*. The hourly rate of glucose consumption was estimated for undiluted normal and parasitized blood on which differential counts were made. The amount of glucose metabolized by reticulocytes was made possible by rendering chickens anaemic through administration of phenylhydrazine. It was found that the adult chicken red cell uses glucose at about one-seventh the rate of reticulocytes. Depending on the stage of development of the parasite, a parasitized cell on average used twice as much glucose as a reticulocyte. A formula was developed, based on several assumptions, by which the glucose consumption of blood with known cell content could be calculated. The results agreed well with theory and the method should be of value in indicating the probable glucose consumption in culture material.

J D Fulton

JOSEPHSON, E S, TAYLOR, D Jane, GREENBERG, J & NADEL, E M. *The Ascorbic Acid Content of the Adrenal Glands of Chicks infected with Plasmodium gallinaceum*. *J National Malaria Soc* 1949, June, v 8, No 2, 132-6, 1 fig [14 refs]

"The adrenal ascorbic acid concentration in the chick, an animal which requires no dietary ascorbic acid, was unchanged during the course of a

blood-induced malarial (*P. gallinaceum*) infection. There was an absolute increase in ascorbic acid per gland proportional to the degree of adrenal hypertrophy observed during the course of the infection.

"Daily injections of 10 mg. of ascorbic acid had no effect upon the course of parasitemia, day of death or degree of adrenal hypertrophy."

"Withholding of food and water from chicks for 5 days resulted in no change in the adrenal ascorbic acid concentration."

BLACKWATER FEVER

TRINÇÃO C. Pode a exanguino-transfusão apagar-se ao tratamento da febre biliosa hemoglobínica? [Can Exchange Transfusion of Blood be of Service in Blackwater Fever? *An Int Med Trop* Lisbon, 1945 Dec., v 5 263-8. (13 refs.) English summary]

By *exanguino transfusão* the author seems to imply the complete substitution of the blood of the donor for that of the patient. Taking the quantity of blood of an adult as 5 000 cc., he says that introduction of three times this amount, with simultaneous withdrawal of that of the patient, will be necessary to replace 85 per cent. of the patient's blood. Among the causes for which such a procedure might be needed is blackwater fever in order to remove the haemolysins circulating in the patient's blood to relieve the patient from metabolizing his haemoglobin and its derivatives set free in the circulation, and, lastly to repair the acute anaemia. He recalls MARGRAVE'S studies: the effect that the anuria of blackwater fever is due to renal anoxia and not to blockage of the renal tubules (see this *Bulletin* 1945 v 42, 10, 938 1947 v 44, 41) and thinks his method worth a trial. One difficulty would be to obtain so large a quantity of the spot as 15 000 cc. of compatible blood. H. Harold Scott

TRYPANOSOMIASIS

KLEVER, Friedrich Karl. Ein deutscher Trypanari.

This book is reviewed on p. 1101

LALOUZ, J. La trypanosomiase dans le Bas-Oubangui de 1907 à 1944. [Trypanosomiasis in Bas-Oubangui (French Equatorial Africa) from 1907 to 1944.] *Bull Soc Path Exot* 1949 42, Nov 54 229-32. (10 refs.)

This is a historical review of the incidence and distribution of sleeping sickness in the Bas-Oubangui or Sangha-Motaba Sector of French Equatorial Africa: the area includes the basins of the rivers Sangha, M'ba and Likouala-aux-Herbes corresponding to the three districts of Impfondo, Dongou and Férre. Prior (this *Bulletin* 1939 16, 34) gave a sketch-map of the area and described it as situated along and to the west of 700 km. of the river Oubangui which separates it from the Belgian Congo. The Sector was created in 1919 but tours of inspection and treatment were made from 1907 to 1948: the results as regards the distribution and incidence are shown in figures, with comments on changes in local populations and on factors influencing the spread of the disease. The number of sleeping cases, the beds

(percentage of the population) of total morbidity, index of new infections, and index of circulating virus (trypanosomes present in the blood) for 1947 were as follows —

	<i>Impfondo</i>	<i>Dongou</i>	<i>Epéna</i>
Number of cases	484	819	629
Index of new cases	2.5	0.4	1.08
Index of circulating virus	2.6	0.4	1.12
Index of total morbidity, theoretical	13	7.4	8.4

A comparison with the figures for previous years shows that on the whole there has been a considerable improvement in the sleeping sickness position in the area
J F Corson

FERREIRA, F S da C Relatório do Chefe da Missão de Estudo e Combate da Doença do Sono na Guiné referente a 1947 [Report of the Head of the Mission for the Study and Campaign against Sleeping Sickness in Portuguese Guinea in 1947] *An Inst Med Trop* Lisbon 1948, Dec, v 5, 407-44, 2 figs

The organization of the work was still incomplete in 1947 owing to shortage of staff and money but more was done than in 1946, 81,042 people were examined and 782 cases of sleeping sickness were diagnosed (in 1946 the corresponding figures were 15,689 and 404). The remaining population not yet examined numbered 250,000. Polymorphic trypanosomes were found in the three species of tsetse flies present, viz *Glossina palpalis*, *G. longipalpis* and *G. submorsitans*, of 1,456 flies dissected 52 (3.6 per cent) showed polymorphic trypanosomes. The sleeping sickness patients were treated by injections of drugs but details and results are not given in this report. The Commission also investigated the prevalence of guinea worm, filariasis, schistosomiasis, ankylostomiasis and leprosy [See also this *Bulletin*, 1948, v 45, 1069-1070, 1949, v 46, 530]

- 1 VANDERPLANK, F L The Classification of *Glossina morsitans* Westwood (Diptera, Muscidae), including a Description of a New Subspecies, Varieties and Hybrids *Proc Roy Entom Soc of London* Ser B 1949, Apr 15, v 18, Pts 3/4, 56-64, 1 map & 3 pls (1 coloured)
- 11 — Variation in the Male Genitalia of the Tsetse Fly *Glossina pallidipes* (Austen) and a Note on *G. austeni* (Newstead) *Ibid* 65-8, 1 map
- 111 — The Classification of *Glossina palpalis*, including the Descriptions of New Subspecies and Hybrids *Ibid* 69-77, 1 fig, 1 map & 2 pls

1 The first paper contains descriptions of a new subspecies of *Glossina morsitans* (*orientalis*), and of three new races of *G. m. submorsitans* (*congolensis*, *ugandensis* and *gambiensis*). Separation into subspecies and races is based on morphological differences in male genitalia. A map shows that these forms of *G. morsitans* are geographically isolated from one another, subspecies *morsitans* occurs in parts of Southern and Northern Rhodesia and in western and central Tanganyika [the distribution in Bechuanaland is not mentioned or shown on the map], subspecies *orientalis* occurs in the eastern parts of Tanganyika, in Nyasaland and in the northern parts of Portuguese East Africa, subspecies *submorsitans* and its race *gambiensis* occupy a belt in West Africa running east from the mouth of the Gambia river to a point south-east of Lake Chad, east of this is a wide gap and then another fly belt, occupied by race *ugandensis* (1289)

running along the Sudan-Congo border country into Uganda race *congoensis* is shown as occurring in a vast area in central and southern Belgian Congo and in the north of Angola.

On the same map the distribution of *G. sawyeri* in Northern Tanganyika is also indicated.

Descriptions are given of hybrids produced by crossing the various forms of *G. morsitans* the abdomens and male genitalia of these are illustrated.

ii. In the second paper the author records that a few cross-breeding experiments between *G. pallidipes* from different areas produced no significant differences in the offspring that he has not yet been able to cross the West African *G. longipalpis* with *G. pallidipes* and that slight differences observed in the male genitalia of *G. austeni* do not suggest that any races of this species exist. A map shows the distribution of these three tsetse flies *G. paludipes* and *G. austeni* in East Africa and *G. longipalpis* mainly in West Africa but also in the south-east corner of Belgian Congo. (In the text it is stated that *G. pallidipes* occurs in Bechuanaland—this is surely an error. It is not marked on the map.)

iii. The third paper is on the same lines as the first. The subspecies of *G. palpalis* which are described are *G. p. palpalis*, *G. p. martinii*, *G. p. fuscipes* and two new ones *G. p. gambiensis* and *G. p. angolensis*. Relevant portions of the male genitalia are illustrated by drawings and by photograph and a map shows the distribution of the subspecies. *G. p. fuscipes* occurs in Southern Sudan and in Uganda. The extensive distribution shown on the map as existing along the courses of the river Nile and its tributaries in the Sudan region of southern Sudan is an error as also is the absence of any indication of the presence of *G. p. fuscipes* along the Sudan-Congo border. *G. p. martinii* occurs along the upper parts of the Congo River and its tributaries around Lake Tanganyika and as far south as Lake Bangweulu in Northern Rhodesia. *G. p. palpalis* is found along the lower reaches of the Congo River and along its northern tributaries along the west coast and the course of the Niger River. Of the two new subspecies, *G. p. angolensis* is distributed along rivers in the west of Angola and *G. p. gambiensis* is found in Gambia and Senegal. The northerly limits of *G. palpalis* in West Africa shown on this map are 1° S beyond those given by Nash (this Bulletin 1949 v. 48 221).

Descriptions are also given of hybrids produced by crossing various subspecies of *G. palpalis* with each other. None of these hybrids likely to be encountered in nature because the subspecies are so widely separated.

The author has deposited his preserved material in the British Museum for future reference. These important papers should be studied in the original by entomologists interested in these flies. H. V. Leeson

JACKSON C. H. V. The Biology of Tsetse Flies. *Bol. Agric.* 1949 Apr. v. 4 No. 1, 174-69. 797 refs.

Selected field and laboratory studies on the biology of tsetse flies are summarized in this review. After the introduction the subject is conveniently dealt with under the following broad reproductive cycle: the teneral fly, the non-teneral fly, digestion, food and feeding habits and sensus and activity. Most of the literature quoted is latest. *Glossina morsitans*, *G. palpalis* and *G. tachinoides* but there are also references to researches on *G. swynnertoni*, *G. austeni*, *G. pallidipes*, *G. longipalpis*, *G. brevipalpis* and *G. fuscipes*. Many of the papers discussed have been abstracted in this Bulletin and some of them are quoted in *Kenya Mosquitoes* No. 2 published in 1946 by The Bureau of Hygiene & Tropical Diseases. It is noted that temperatures are given in degrees Centigrade.

The reproductive cycle of tsetse flies varies with the temperature but not with the humidity. At 23° [C] it occupies a minimum period of 55 days, 33 of which are spent as pupae. Pupae are able to withstand slight frost and development proceeds at temperatures between 16° and 31° [C], at temperatures above 40° [C] they are killed after various periods of exposure. The natural pupal mortality rate varies from zero to 50 per cent according to temperature.

Adults of some species tolerate slight frost for short times, exposures to 38° [C] or over may be lethal especially if the humidity is high. *Glossina morsitans* and *G. swynnertoni* may live about four weeks in nature but at low temperatures survival depends on saturation deficit. Females commonly live twice as long as males. *G. morsitans*, *G. palpalis* and *G. tachinoides* are most active at about 27° [C] and are inactive outside the limits 15.5° and 41.5° [C].

G. swynnertoni, *G. longipalpis* and *G. pallidipes*, and to a great extent *G. morsitans*, have a mammalian diet, while *G. palpalis* and *G. tachinoides* take much nucleated blood and are scarcely affected by the absence of ungulates. *G. pallidipes* is only slightly attracted to man and is active on moonlight nights, *G. austeni* is often active in complete darkness.

These are only a few of the points touched on in this summary which concludes with a valuable list of the most important works on the subject of biology of tsetse flies from 1907 to 1948. H S Leeson

MEM ACAD SCI IST BOLOGNA 1946-47, Ser 10, v 4, 19 pp, 2 figs

Descrizione della prima infezione contratta in laboratorio da *Trypanosoma evansi*. [First recorded (Human) Laboratory Infection by *Trypanosoma evansi*]

This record is of historical interest. In April, 1912, Professor Lanfranchi was studying animal trypanosomes, *T. brucei* and *T. evansi*. He was drawing up blood from a heavily infected guinea-pig with a pipette when the cotton-wool plug became dislodged and, soaked in blood, entered his mouth. He was suffering at the time with an ulcerated left tonsil. He spat out the plug but continued at his work thinking that there was no risk as the trypanosome with which he was working was "an animal trypanosome and not pathogenic for man". Later he gargled. Thereafter, he suffered from access of fever (there had been rise of temperature for some time owing to the tonsillitis) and sweats "so profuse that it passed through the mattress and wetted the floor" [as mentioned below the patient's recollection for recent events at the time was poor], insomnia, tachycardia paroxysmal in character, enlargement of liver and spleen and lymphatic glands, with loss of memory for recent events and pain in the thumbs and forearms sufficiently acute in the right to prevent his using the right hand for picking up and holding objects. Trypanosomes were present in his blood and these were measured by Mesnil and others, much detail is given of the comparison between these and those of human sleeping sickness (called in this paper Castellanosis). Treatment by atoxyl brought about cure. By measurements and by serological tests Professor Mesnil concluded that the trypanosome which infected Professor Lanfranchi was *T. evansi*.

LE ROUZIC, J. Deuxième note sur les premiers essais de chimio-prophylaxie en Afrique Occidentale Française par la Pentamidine. [Second Note on the First Trials of Pentamidine as a Prophylactic Agent against Sleeping Sickness in French West Africa] *Bull. Méd. de l'Afrique Occidentale Française* 1948, v 5, No 1, 89-91.

Later results are given of the field experiment on pentamidine prophylaxis described by BRUN-BUISSON *et al* [this *Bulletin*, 1949, v 46, 123]. The previous

report showed that six months after prophylactic treatment no infection was discovered among 1 002 treated persons while there were 19 cases among the 800 controls (2.1 per cent. infection rate). A follow-up 12 months after treatment now shows only three new cases among the treated persons (0.29 per cent. infection rate) and 24 among the controls (3.1 per cent. infection rate).

In view of these favourable results, this form of chemoprophylaxis is to be applied to 15 000 people in the forest regions of Guinea and Casamance.

E. M. Lewis

OSTERLIN, M. Beitrag zum Problem der Arzneimittelresistenz bei Trypanosomen.
[Contribution on the Problem of Drug Resistance in Trypanosomes.]
Zent.f. Bakt. I Abt. Orig. 1941 Aug. 1 147 No. 5 315-8.

The author discusses the relationship between certain types of chemotherapeutic interference and acquired drug-resistance. For interference the point of fixation of the drug on the trypanosome is presumed to have been impaired by the interfering substance while for resistance the same point of fixation has been unimpaired by the chemotherapeutic agent itself. Somewhat tenuous reasoning then leads the author to expect that by exposing arsenic-resistant trypanosomes to potassium hexatantalate the resistance might be reduced. The main points of the argument seem to be—

(i) The impairment of the trypanosome's receptors which gives rise to resistance is a mechanism of self protection on the part of the trypanosome cell.

(ii) Potassium hexatantalate damages the protective mechanisms of laboratory animals (by interfering with phagocytosis).

(iii) Why then, should it not upset also the protective mechanisms of humbler creatures, i.e. resistant trypanosomes especially, since it may be assumed from interference experiments (BLOKCHAUSS and ROSETHAL *Surfing Sickness Bulletin* 1911 v. 3 115 and 201 SCHWITZER and SILVERSTEIN *this Bulletin* 1927 v. 24 571) that the trypanosome cell has the same points of attachment for potassium hexatantalate as for certain arsenicals and antimonial salts?

(iv) Potassium hexatantalate is readily diffusible and so should be readily absorbed by the trypanosome cell thus providing an excellent opportunity for exercising its influence.

Trypanosomes were separated by centrifugation from heavily infected mouse blood and washed two or three times in Ringer solution containing 0.1 per cent glucose until the surrounding fluid was free of protein. They were then suspended for 1 to 2 hours (temperature not stated) in a solution containing 0.9 per cent sodium chloride 0.1 per cent glucose and 0.1 per cent Tantalum Chloride (A. G.) after which they were inoculated into fresh animals.

In this way the resistance was found to be diminished after 4 to 7 passages (presumably repeating the above procedure after each passage though this is not explicitly stated). With restored arsenic sensitivity there was also restoration of the trypanosome's property of fluorescence on contact with trypanflavin or trykumoline. The trypanosome now is believed merely as *dearsensifizierte* (from 128 der 1 G. *Lebensmittel* 1941).

[These are very interesting findings. Nothing is said as to how long the restored arsenic sensitivity lasted on a frequent repeated animal passage. To cause permanent disappearance of drug resistance would be considerable achievement. For progress that in this direction see 1941 v. this Bulletin 1940 37 B.R.]

LEÓN, L. A. Información sobre el problema de la enfermedad de Chagas en el Ecuador [Report on the Chagas's Disease Problem] *Bol Oficina Sanitaria Panamericana* 1949, June, v 28, No 6, 569-85, 1 map [25 refs] English summary

This account is of considerable interest, historically, epidemiologically and entomologically. Chagas's disease has probably existed in Ecuador for a long time, for *Triatoma dimidiata*, the common vector there, was recorded by Stål in Guayaquil nearly 100 years ago. In 1921, RUBIO observed a rare form of palpebral oedema [now known as Romaña's sign] and VALENZUELA suggested the existence of the disease there. Nevertheless the infection is not rife. In the last 20 years only 18 cases have been reported, 9 of either sex, 10 in adults, 8 in children, 14 acute cases and 4 chronic and, so far, only one fatal. Five species of *Triatoma* are found in Ecuador. *T. dimidiata*, the chief vector. Crespo in 1947 found 25.9 per cent of 748 positive in Guayaquil. *T. d. capitata*, really a subspecies of the last, has been found naturally infected and is easily infectable in the laboratory. *T. carrioni*, also infectable experimentally. *Mestor* (*Panstrongylus*) *rufotuberculatus*, probably synonymous with *T. coxoriufa*, has been found naturally infected. *T. venenosa*, found in Costa Rica, Panama, Colombia and elsewhere, but rare in Ecuador and, if potentially a vector, is of little importance there. *Rhodnius prolixus* has also been found in Ecuador, being a known vector elsewhere, it may be, and probably is, so here also. The chief reservoir host is said to be *Didelphys azarac* [misspelt *azarca*] Azara's opossum [called in this paper a fox] or *D. paraguayensis*. Though cases are not many, it is said that the infection is spreading and the Government is urged to take steps in time to improve the housing and to get rid of the insect vectors.

PINTO, C. Factos curiosos sobre a biologia do "*Triatoma sordida*" Nota Prévia [Some Interesting Facts about the Biology of the "*Triatoma sordida*"] *Rev Brasileira Med* Rio de Janeiro 1949, May, v 6, No 5, 305

The English summary appended to the paper is as follows —

"1 *Triatoma sordida*, one of the transmitters of Carlos Chagas disease (Trypanosomiasis cruzi) is capable of laying eggs through meshes of about one square millimeter. These eggs can be projected at one inch distance out of the vessel where females are kept.

"2 The complete evolutionary cycle of *Triatoma sordida* takes only five months from egg to egg, and took place from September to February in laboratory cultures kept in Rio de Janeiro."

CORNEJO, A. Enfermedad de Chagas-Mazza. Xenodiagnostico. Modificación de Borzone al método de Brumpt [Chagas's Disease. Borzone's Modification of Brumpt's Method of Xenodiagnosis] *Semana Méd* 1949, July 28, v 56, No 30, 181-3, 4 figs

Brumpt's original method of applying to the forearm of the patient the uninfected bugs in a Mazza apparatus covered with gauze was modified by Romaña and Gil who used a test-tube whose mouth was covered by the skin of a recently killed mouse or guinea-pig, the tube containing a sample of the suspected blood, defibrinated or citrated, and introduced this into one with a wider mouth containing 5 or 6 of the bugs to be infected. Borzone's modification consists in collecting 10 cc of blood in a dry syringe. When the blood reaches the laboratory it is placed in a watch-glass or some such receptacle.

and 4-6 larvae of *Triatoma s. fedians* feed on it under cover of a bell-jar and some dark material to resemble night time during which the insects usually bite. When engorged they are set apart at 37°C. and their faeces can be examined from time to time during the 2 months for which the vectors are usually kept before final testing for diagnosis. *H. Harold Scott*

LEISHMANIASIS

Travoso C. A inoculação da *Leishmania donovani* em cultura in vitro da medula óssea e nos ovos embrionados de galinha. [Inoculation of Bone-Marrow and of Fertilized Hen-Eggs with *Leishmania donovani*] *Rev. Inst. Med. Trop. Lisbon*, 1948, Dec. v 5 141-7, 1 pl. (15 refs.) English summary (5 lines)

Several investigators have found that when *Leishmania* were inoculated into tissue cultures their survival time was inverse to the rapidity of growth of the tissue whereas in the yolk-sac of the hen's egg they developed well. The author's studies have confirmed these findings. In the first 24 hours of the marrow cultures the leptomorphous forms appeared to increase in numbers but after 24 hours they became scarce and in 2 days none could be seen. The marrow of a healthy person was tried first and then that of one with myeloma, but the results were the same. The question arose: Was this due to the medium being unsuitable or was it due to phagocytosis? Closer study showed that phagocytosis was intense and early and the phagocytes themselves then rapidly degenerated.

With fertilized eggs the results were very different. Six-day-old fertilized eggs were inoculated in the yolk sac and inoculated at 37°C. When they were examined on the 20th day leptomorphous forms were numerous and the normal development of the embryos had not been checked in any way. Such a method would seem therefore to be an excellent one for preserving strains in the laboratory. *H. Harold Scott*

Fraga L. C. & Li W. C. The Survival of *Leishmania donovani* in *Oryzias latipes* monohits. Reprinted from *Peking Natural History Bull.* 1949 v 17 No. 4 741-3. 10 refs.

1. Experiments showed that *Leishmania donovani* could live in the gut of *O. monohits* for at least 25 days.
2. The *Leishmania* parasites did not develop into flagellates in the tick.

Travoso C. Valor da cloro-hidrólise do soro no diagnóstico da kala-azar. [The Value of the Hydrochloric Acid Gelification Reaction in the Diagnosis of Kala Azar.] *Rev. Inst. Med. Trop. Lisbon*, 1948, Dec. v 5 135-6. 11 refs. English summary (9 lines)

[See this Bulletin 1949, 44, 137]

Travoso C. A siderémia na kala-azar. Serum Iron in Kala Azar. *Rev. Inst. Med. Trop. Lisbon*, 1949, Dec. v 5 131-4. 11 refs.

The English summary appended to the paper is as follows:

"The determination of the serum iron in 16 cases of acute leishmaniasis demonstrates that in every case the serum iron values are normal or increased. Consequently a defect in the iron absorption cannot explain the anemia of the disease."

TRINCÃO, C. O mielograma no kala-azar [The Myelogram in Kala Azar]
An Inst Med Trop Lisbon 1948, Dec, v 5, 99-118 [46 refs]

The English summary appended to the paper is as follows —

"The writer studies the sternal marrow pattern in 5 cases of visceral leishmaniasis of the adult. In every case the bone marrow was active, but the ripening and mitoses curves demonstrated an inhibition of the blood cell production"

TRINCÃO, C. O esplenograma no kala-azar [The Splenogram in Kala Azar]
An Inst Med Trop Lisbon 1948, Dec, v 5, 119-29 [17 refs]

The English summary appended to the paper is as follows —

"The author studies the splenic picture of 13 cases of visceral leishmaniasis, 3 of which were in adult patients. The differential counts vary widely. The number of reticulo-endothelial cells, erythroblasts and granuloblasts is increased"

RUCCI, E. Emazie a bersaglio nella leishmaniosi viscerale umana [Target Cells in Kala Azar] *Acta Med Italica* 1949, July, v 4, No 7, 169-70.

The English summary appended to the paper is as follows —

"The picture of red cells 'a bersaglio' [target cells] has already been described in the haemoparasitosis (leucocytegregrinose, trypanosomiasis of the animals, human malaria) the author describes the same picture in the visceral leishmaniasis of the children. The picture is demonstrable in the spleen and not in the peripheral blood"

LEONARDI, G & PINNA, R. Sui risultati terapeutici dell'antimoniato di N-metilglucamina in un caso di leishmaniosi viscerale resistente al tartrato di sodio e antimonio [Treatment of a Case of Visceral Leishmaniasis by N-methylglucamine of Antimony] *Acta Med Italica* 1949, June, v 4, No 6, 147-50, 1 fig [17 refs] English summary

The usefulness of antimonials in certain tropical diseases is well known but, owing to low grades of tolerance or fear of symptoms of intolerance in even therapeutic doses, new compounds are constantly being manufactured and tried. The patient whose case is recorded here was a man of 35 years who had had malaria in 1946 and recovered. In June 1948 he suffered from fever and sweats which continued intermittently and in September he had pain in the left hypochondrium, the spleen was found to be enlarged and puncture revealed leishmania. Sternal puncture showed that the marrow was crowded with leishmania. He was given intensive treatment with sodium antimony tartrate [dosage not stated], but without effect and a new pentavalent antimonial was tried, *Glucantim* or N-methyl-glucamine antimoniate, injected intramuscularly, 10 cc of a 30 per cent solution. The preparation itself contains 28.35 per cent of antimony and doses of 15 and even 20 cc a day were well tolerated. Altogether "22.55 gm of Sb were given in 18 days" [sic, these are the figures presented, but it seems incredible that such very large doses of antimony could be given. See this *Bulletin*, 1947, v 44, 56]. The splenic enlargement began to show reduction after a very few days and within a fortnight had receded almost to the costal margin, leucocytes had risen to 5,000 per cmm, differential count gave polymorphonuclears 38, large mononuclears 8, lymphocytes 51, eosinophiles 3 per cent. Red corpuscles

numbered 2,490,000 Hb. 56 per cent., and the patient's general condition improved rapidly. Examination of the bone marrow revealed a marked reduction of leishmania on the 1st day and none on the 18th day.

H Harold Scott

12. SOUSA, M. T. & DE ALMEIDA, L. Kala azar infantil stibio-resistente. Tratamento pela lomildine. [A Case of Infantile Kala Azar resistant to Antimony treated with Lomildine. *Rev. Med. Portuguesa* 1949 v. 2, No. 4, 481-8, 1 fig. [?1 refs.]

It has been said that if cases of infantile kala azar were reported as resistant to antimony this was due to the dosage being inadequate. This charge can certainly not apply to the patient whose case is described here. Clinically, it was typical and the description is given in much detail with the results of repeated blood examination. This may be summarized by saying that in spite of repeated courses of injections of neostibosan and blood transfusions after slight transient improvement the condition became gradually worse till the child's state was very precarious. Red cells were down to 1,800,000, leucocytes 2,400 per cmm. Hb. 40 per cent., neutrophils 33, eosinophils 1, lymphocytes 62, platelets 1, metamyelocytes 3 per cent. A fresh drug was then tried antimonate of N-methylglucamine known commercially as Glucantone but a week later the corpuscles had fallen to 1,350,000 and the Hb. to 30 per cent. A new drug was then given a triol dimethanesulphonate of 4-4'-diaminodiphenyl pentane or commercially Lomildine. This was given intramuscularly for 15 doses on alternate days in a 2 per cent. solution in physiological saline starting with 0.5 cc. then 0.5, 1.0, 1.5 cc. etc. to 3.0 cc. At the same time the patient was given liver extract, iron and vitamins B₂ and C. In 3 weeks the temperature which had been falling gradually came to normal, the red cell count increased steadily and in 3½ months the corpuscles numbered 1,100,000 leucocytes 4,000 per cmm. Hb. 65 per cent. A second series of 14 injections had been started after an interval of 17 days, beginning with 1 cc. of the 2 per cent. solution and rising to 3 cc. After another interval, of 40 days a third course was given although everything appeared to be going well and the blood count then gave red cells 9,000,000 leucocytes 5,000 per cmm. Hb. 70 per cent. (Sabb) the general condition was good, the spleen palpable but only 2 cm. below the costal margin and the child's weight had increased by 17.5 kgm.

CORRADETTI, A. Studi sulla epidemiologia della leishmaniosi cutanea nella regione del medio Adriatico. I. Incidenza della leishmaniosi cutanea nella zona compresa tra il Tordino e il Vomano. [Epidemiology of Cutaneous Leishmaniasis in the Adriatic Region. I. Incidence in the Zone between the Tordino and Vomano Rivers. *Riv. di Pat. int.* Rome 1948 Dec. v. 9, No. 4, 227-8.

The English summary appended to the paper is as follows:—

An epidemiological survey in the province of Teramo (Abruzzi) has shown that of 28,599 people examined 6,700 (23.7%) were affected by either actual (7.9%) or suspected (20.8%) cutaneous leishmaniasis.

FOURIE, M. A. Jr. Exogenous Cutaneous Leishmaniasis proved by Culture. *Arch. Dermat. & Syph.* 1949 Sept. 48, No. 3, 301-7. (Ref. in footnote.)

A short account of the history of this disease is given. This is a reference to CRANE, CHAM (1935) the author writes: "In England I have led the histologic

picture and stated that there were bodies within the cells which were circular to elliptic in shape" Actually, in an illustration in Cunningham's paper, these bodies are shown, they are typical leishmania]

This is followed by a short description of a case of oriental sore in a student from Aleppo, Syria. He left Aleppo in August 1946. In February and March, 1947, respectively, small lesions, red papules, appeared on the dorsum of his left hand and left ear. These developed into typical orientalsores. Smears showed leishmania. Later, cultures were taken by injecting isotonic saline into the periphery of the lesions and withdrawing it, this material was inoculated into NNH medium and flagellates developed.

The lesions were surgically excised with 1 cm of normal skin surrounding them. The wounds healed, but six months later a small nodule appeared 1 cm proximal to the operation scar on the left hand. This also showed leishmania, but 4 months later it had healed spontaneously.

The author discusses the dangers of the disease becoming endemic in the United States, and the importance of cultural methods to confirm the diagnosis. In support of the latter point, he quotes DOSTROVSKY & SAGHER [this *Bulletin*, 1947, v 44, 1056]. [In view of the absence of any known vectors and the rarity of all *Phlebotomus* species in the United States, the danger of the establishment of this disease can scarcely be very real, and culture is surely unnecessary where unmistakable leishmania, e.g. as shown in the illustration accompanying the author's paper, are found in smears. The main point of the writers quoted was that cultures are frequently positive in the absence of leishmania in the smears.]

FEVERS OF THE TYPHUS GROUP

PRATT, E P, DRYSDALE, A. D & KIRK, R. Typhus Fevers in the Anglo-Egyptian Sudan. *J Trop Med & Hyg.* 1949, Aug, v 52, No 8, 157-60.

Fevers of the typhus group are rare in the Anglo-Egyptian Sudan, between 1898 and 1941 there is no record of the occurrence of any case.

In 1937 Weil-Felix tests were carried out on 1,000 sera sent from all parts of the Sudan for the Kahn or Widal tests, for investigation in cases of fever of unknown origin, or for the purposes of the special enquiry. Only two positive reactions were obtained, in one case the titre with *Proteus* OXK was 1-500, and in the other there was a *Pr* OX2 reaction at 1-250. In neither case could the significance of the reaction be determined.

Sera of 240 rats were tested, none was positive at a titre of 1-50 with any strain of *Proteus*.

In 1939 sera of 222 persons were tested against *Pr* OXK in connexion with the investigation of trachoma, one woman, aged 80, reacted at a titre of 1-125, but no association with a typhus fever could be discovered.

Two cases already reported are mentioned, one was a case which occurred in Juba in 1941 and was described by SOMERS as one of tick typhus, with a *Pr* OX2 reaction of 1-1,250 and a *tache noire*. [See this *Bulletin*, 1946, v 43, 327] the other was a case which occurred in 1943 in the Gezira region, described by STEPHENSON as a problem case with a *Pr* OXK titre of 1-2,500 [See this *Bulletin*, 1945, v 42, 553].

In 1943 an isolated case of typical typhus occurred in Khartoum the *Pr* OX19 titre was 1-500 but the source of infection could not be discovered.

In 1943-44 there were 22 cases of house-borne typhus in Wadi Halfa on the Egyptian border these were obviously associated with the epidemic in Egypt. Rigorous precautions were taken to prevent the spread of infection and no further case occurred in the Sudan.

KAYŃSKI S & WOJCICHOWSKA, S. Investigation into the Problem of Artificial Feeding of Lice by way of Intrarectal Injections as applied by Weigl. *Bull. Inst. Marine & Trop. Med. Med. Acad. Gdansk Poland* 1949, 2, No. 1/2, 69-80.

Those interested in the cultivation of rickettsiae in lice will find a number of useful hints in this note.

In the artificial feeding of the insects *for rectum* stress is laid on the importance of haemoglobin and glucose as ingredients of the nutritive ementa.

John H. D. Meyer

KAYŃSKI S & WOJCICHOWSKA, S. Influence of various factors upon Virulence and Viability of *R. prowazeki* in Laboratory Breeding by Weigl's Method. *Bull. Inst. Marine & Trop. Med. Med. Acad. Gdansk Poland* 1949, 2, No. 1/2, 49-58 - charts.

Great variations were observed in the virulence to lice of different strains of *Rickettsia prowazeki* which were repeatedly passaged through lice by Weigl's method, but after a long series of passages the variations in virulence became much less.

No association with seasonal influences could be detected to account for the changes in virulence and rate of growth occurring during repeated passages through lice.

The author studied the influence of various factors on virulence including the rickettsial concentration of the suspensions used, for 1/100 of the period of retention of the inoculum in the lice exposure to light, action of phenol, methylene blue and copper presumably copper sulphate.

John H. D. Meyer

VINGUYR, E. *Intérêt de la technique cutanée dans le dosage comparé des rickettsies.* (Points connected with the Intracutaneous Technique in the Estimation of the Comparative Virulence of Rickettsiae. 4th Int. Symp. 1949 May, 78, No. 5, 462-5).

Suspensions of three strains of *Rickettsia prowazeki* were tested by the Guérin's intradermal test. It was found that suspension made in milk diluted egg-white or nutrient broth were more suitable for maintaining the virulence of the rickettsiae than those made in distilled water or in glucose water.

The former group of suspensions when hypodermally injected into guinea pigs were found to be more suitable for use in the test than those prepared in any suitable medium.

John H. D. Meyer

BRILL, G. H. & OHLING, Lily. *Indurating Antigens of Rickettsiae*. *J. Biol. Chem.* 1949 Aug. 1, 178, No. 2, 45-51.

By immunizing rabbits with the non-indurating supernatant fluid obtained by centrifuging fresh suspensions of living *Rickettsia prowazeki* serum was obtained which was capable of neutralizing rickettsial suspensions by mixing them into tubes.

The serum also had pronounced anti-infectious properties, though these were not so great as those of standard immune sera

The serum when added to rickettsial suspensions, whether fresh or after treatment by heat or disinfectants, converted the toxic factor to a toxoid, so that it is possible to prepare a vaccine of high potency and low toxicity

For details of the experiments the original paper must be consulted

FRANK, H R Die Serumtherapie des klassischen und murinen Fleckfiebers Grundlagen, Ergebnisse, Indikation [Serum Therapy of Classical and Murine Typhus] *Ztschr f Hyg u Infektionskr* 1948, Aug 17, v 128, Nos 3/4, 294-330, 1 fig [125 refs]

This paper is really a comprehensive, though concise, monograph on the serum therapy of louse-borne and murine typhus In two bibliographies there are 125 references to the literature up to the year 1948

The author's personal experience is described in six pages out of the 36 of which the paper consists Altogether 22 patients were treated but only eight of the cases are described, in these the treatment was started before the appearance of a rash, which, in fact, never developed in unmistakable form, presumably because of the inhibiting action of the serum The diagnosis was confirmed by the occurrence of a rising-titre Weil-Felix reaction which was positive with dilutions of 1-1,600 to 1-6,400 Two of these cases are of special interest, the treatment was started on the 2nd day with intravenous doses of 99 and 90 cc of convalescent serum, and further doses ranging from 52 to 120 cc were given on each of the following two days In both cases the temperature fell nearly to normal two days after the first dose was given and remained nearly normal till the 8th and 9th days, respectively, when there was a further spell of fever which lasted two days in each case and apparently yielded to two additional doses of serum

All but one of the other six cases belonging to this group were very mild, but three of them had been inoculated and in one of the uninoculated patients a high temperature persisted till the 8th day in spite of two injections of serum given on the 4th and 5th days

Little is said of the 14 cases in which the treatment was started after the appearance of the rash, from a table it appears that the average duration of the fever was 14.6 days, almost the same as in the 26 untreated controls in which it was 14.9 days

The rest of the article consists of a critical, fully documented, review of the literature The conclusions reached were that serum treatment started before the appearance of the rash was strikingly effective and that there were clear indications of its value up to the 5th day Treatment started between the 5th and 9th days appeared in some cases to have had a favourable effect, but after the 10th day it was useless

[The situation was greatly changed since the author wrote the present article The proved efficacy of chloromycetin and aureomycin is likely to discourage the use of specific antisera, especially as these have a restricted sphere of efficacy and availability]

PEREIRA, H G, TRAVASSOS, J & VASCONCELOS, J V Tifo murino no Rio de Janeiro I Ocorrência de ratos naturalmente infectados [Murine Typhus in Rio de Janeiro Natural Infection among Rats] *Hospital Rio de Janeiro* 1949, May, v 35, No 5, 679-87 [11 refs] English summary

Nine out of the first 50 rats examined by the authors in Rio de Janeiro gave positive reactions with the complement-fixation and rickettsia-agglutination

tests for murine typhus. Two strains of *Rickettsia mooseri* were isolated from the sera of the only four reacting rats that were tested by guinea-pig inoculation. Each strain was obtained from the pooled sera of two rats.

Only four of the nine reacting rats gave positive Weil-Felix reactions, at titres of 1-80, 1-320, 1-320 and 1-640 respectively, and only two of these four had given positive reactions with the other tests. An attempt was made without success, to isolate rickettsiae from the rat whose Weil-Felix titre was 1-640; this was one of the rats that gave negative reactions with the other tests.

There was a striking degree of correlation between the complement fixation and rickettsia agglutination tests: the titres observed were 1-20 to 1-320 with the former and 1-40 to 1-320 with the latter test.

GISPEX R., SMIT A. M. & WESTERHOF C. D. Epidemic Scrub Typhus in Batavia. *Documenta Neerlandica et Indonemica de Morbis Propriis*. Amsterdam, 1949. June v. 1 No. 1, 131-41. 1 fig. (1 refs.)

The author describes an outbreak of scrub typhus in which 20 persons living in Batavia City were attacked between December 1947 and May 1949. There were probably many more cases which were not detected.

The Weil-Felix titres (*Proctus OAK*) ranged from 1-800 to 1-6,400; an echard occurred in four cases, and rickettsiae were isolated from two of the patients.

Although the outbreak was in an urban area 13 of 15 patients whose previous movements were known had been in close contact with tall *alang gram* (referred to as *alang gram* in many reports) growing by the side of a canal, so that the disease occurred in association with conditions of the rural type.

Rats infested with *Trombididae* larvae were caught in and near the houses at the border of the grassy area.

JOHNS H. L. Jr & KING, J. A. Tsurugamushi Disease. Report of a Case. *U.S. War Med. Bull.* 1949, July-Aug. v. 49 No. 4, 71-5. (10 refs.)

A case of tsurugamushi disease (scrub typhus) is presented. Among the unusual features encountered were: (a) the petechiae on the buccal mucosa; (b) the presence of a positive Weil-Felix, OAK, in the patient's dog; and (c) the important epidemiological fact that this is the first authenticated case, to our knowledge, that has been reported in China.

HAYASHI, H. & WATANABE, M. On the Possibility of Appearance of Rickettsiae in the Circulating Blood after the Recovery of (from) Rickettsiosis. *Akiyama Arch. Exper. Med.* 1949, Nov. v. 1 No. 2, 133-41.

The blood of a patient convalescent from an attack of tsurugamushi disease was found infective up to at least 8 days after defervescence. The patient had been inoculated for therapeutic purposes with the Escardoux strain of rickettsia, and infectivity was tested at intervals. On each occasion, dose of typhoid vaccine was given and the blood sample was taken two hours after the end of the febrile reaction that resulted. On three different occasions, person inoculated intravenously and subcutaneously with the blood developed a typical attack of tsurugamushi disease with a rising titre Weil-Felix reaction of the *Proctus OAK* type.

In another experiment on the same lines a person inoculated with blood from an infected patient 34 days after defervescence developed a very mild

attack, but by a series of passages, first through a rat and then through a series of mice, rickettsiae were isolated

John W D Megaw

SMADAL, J E, JACKSON, Elizabeth B & CRUISE, Anita B Chloromycetin in Experimental Rickettsial Infections *J Immunology* 1949, May, v 62, No 1, 49-65, 2 figs [15 refs]

Chloromycetin was shown to have a pronounced rickettsiostatic action when introduced into chick embryos infected with *Rickettsia tsutsugamushi* [orientalis] *R mooseri*, *R akari*, *R prowazeki*, and *R burneti*

The average prolongation of the life of the embryos was usually slightly greater when the injections were made half an hour before inoculation with the infecting rickettsiae than in those injected 24 or 48 hours after inoculation, but in the case of *R burneti* the prolongation was greatest in a batch of embryos treated 42 hours after inoculation

Mice infected with lethal doses of the Karp and Kostival strains of *R tsutsugamushi* nearly always survived after treatment with suitable doses of the drug, given intraperitoneally or orally The Serangayee and Bue strains were much more resistant to the drug, which had to be given in larger doses and for longer periods to obtain effective action The response to treatment of the other strains tested was intermediate between that of the above two pairs of strains

Rickettsiae could be recovered from the tissues of successfully treated mice, in one case up to 100 days after infection, although the treatment was continued throughout the whole period

Mice infected with *R akari* and *R mooseri*, and guinea pigs infected with *R rickettsi*, responded well to the treatment, but contrary to what happened with *R tsutsugamushi*, rickettsiae could not be recovered from the tissues of the animals *R rickettsi* did not respond as well as the others

The drug had no rickettsiacidal action *in vitro* on *R tsutsugamushi*

Blood levels of the drug in mice, treated intraperitoneally, were tested at frequent intervals, the maximum level was reached in about half an hour and then fell rapidly, reaching negligible proportions within three or four hours

Full details of the numerous experiments carried out by the authors will be found in the paper

John W D Megaw

PRATT, H D, LANE, J E & HARMSTON F C New Locality Records for *Allodermanyssus sanguineus*, Vector of Rickettsialpox *J Econom Entom* 1949, June, v 42, No 3, 414-15, 1 fig

The findings were in named areas in Illinois and Utah

GEAR, J & HARRINGTON, A L Tick-Bite Fever - Two Cases treated with Aureomycin (Lederle), a New Antibiotic *South African Med J* 1949, June 25, v 23, No 26, 507-8, 2 figs

Strikingly good results were obtained by aureomycin treatment in two cases of tick-bite fever, "the variety of tick typhus occurring in South Africa."

Treatment, by the mouth, was started on the 4th day in one case and on the 5th day in the other In both cases there was rapid amelioration of the symptoms, fading of the rash, and a fall to normal of the temperature within two days

One of the patients, aged 17, received a total quantity of 4.0 gm given in doses of 250 mgm every four hours, the other patient, aged 4½ years, received 2.25 gm in doses of 250 mgm in syrup thrice daily for three days

The drug was given in doses considerably smaller than those employed by Ross *et al.* in cases of Rocky Mountain spotted fever (see this *Bulletin*, 1949 v 46 357).

[The efficacy of small doses is an important point in view of reports of reactions which though usually slight apparently may in rare cases be severe or even fatal (see this *Bulletin* 1949 v 46 25).] John H. D. Meyer

LIPPETT H. & CASTLETT F. H. Zur Komplement Bindung des Q-Fiebers. (Complement Fixation in Q Fever) *Deut. med. Woch.* 1949 July 29 v 74 No. 29 918-19

The authors describe the confirmation by complement fixation tests of the diagnosis of Q fever as the cause of the laboratory outbreak which occurred at Hamburg in 1947-48 (see this *Bulletin* 1949 v 46, 628).

The antigen employed was the Italian (Hentzerling) strain of *Rickettsia burnetii* obtained from the Bethesda, U.S.A., laboratory.

Apparently every person engaged in handling the strains isolated in the Hamburg laboratory became infected. The only one who appeared to have escaped still gave a positive reaction. John H. D. Meyer

KLORSTOCK, A. KLORSTOCK E. & ROSENKRANZ G. The First Diagnosed Outbreak of Q-Fever in Israel. *Harefuah* Jerusalem, 1949 July 1 v 7 No. 1 In Hebrew 12. English summary —]

During this outbreak, positive complement-fixation tests with *R. burnetii* (Italian strain) were obtained in 5 of 234 sera in titres of 1/32 to 1/2048. In four cases, four to 64 fold rises in titre occurred. In five the reaction rose from negative to 1/128.

Most of the cases occurred in Haifa and were chiefly in males. There appeared to be no contact with cows or goats in most cases and as the outbreak started in winter ticks and other insects could be excluded as vectors. Dust from material handled in Haifa might account for the infection but no source has yet been determined. The outbreak has been non-epidemic and protracted over several months. Most of the negative sera were from cases of atypical pneumonia. H. J. O'D. Burke-Gaffney

WEGMANN T. Encephalitis nach Q-Fever. Encephalitis after Q-Fever. *Schweiz. med. Woch.* 1949 July 30 v 79 No. 30 690-92, 16 15 r 15

The first recorded case of encephalitis after Q fever is described. The onset was eight days after deferrescence from a proved attack which lasted ten days. The first symptom was tremor of the right hand. Soon there were 6 paresthesia, involution of the sleep period, diminished sensibility to touch over the right hand and arm, slurring speech, and exaggeration of knee jerks. The attack lasted about six weeks. Recovery was complete.

The disease is believed to be similar to the encephalitis known to follow smallpox vaccination, measles, rubella, varicella, parotitis, influenza and other virus diseases. The author inclines to the view that the condition is one of neuro-allergy associated with the antigen-antibody reaction. John H. D. Meyer

ALVAREZ, D. M. La fiebre de Dallas como problema fronterizo. Bull. Fed. 25 6. Border Problem. *Del Oficina Sanitaria P. americana* 1949, July 25. No. 7 696-701 1 map. English summary

BARTONELLOSIS

CORRADETTI, A. Esperimento di prevenzione della verruga peruviana e della malaria nella valle del Rio Santa Eulalia (Perù) [Experiment in Prevention of Verruga Peruviana and of Malaria in the St Eulalia Valley, Peru] *Riv di Parassit* Rome 1949, Mar, v 10, No 1, 53-8, 3 figs English summary (4 lines)

In 1947 work was started on the construction of a new pipeline, to reinforce the hydro-electric power supply of the City of Lima, in the Valley of Santa Eulalia. The River Santa Eulalia flows south-west to join the River Rimac, at an altitude of 1,000 metres, 50 kilometres from Lima. Work was concentrated in the lower 20 kilometres of the Valley, up to a height of about 1,800 metres. Both verruga peruviana and malaria are notoriously prevalent in the Santa Eulalia Valley. The problem was to protect the labour force from infection by both these diseases, 3,185 persons were involved. The two disease vectors concerned were *Anopheles pseudopunctipennis* and *Phlebotomus verrucarum*.

In March and April all the dwellings, huts and animal houses in the area were sprayed internally with DDT, 2.5 gm per square metre of surface treated. External walls that furnished a favourable habitat for phlebotomus were sprayed with a slightly higher concentration of DDT. In August the spraying of houses was repeated, 1.29 gm per square metre.

Constant inspection failed to find *A. pseudopunctipennis* in the dwellings during this period and sandflies disappeared suddenly after the spraying. Protection from both diseases was complete.

Norman White

YELLOW FEVER

KUMM, H. W. Estudos da febre amarela silvestre no Brasil durante os dez últimos anos [Studies on Jungle Yellow Fever in Brazil during the Past Ten Years] Reprinted from *Anais do VII Congresso Brasileiro de Higiene, reunido em São Paulo, de 12 a 19 de dezembro de 1948* 9 pp, 4 maps [32 refs]

This paper was presented at the Seventh Brazilian Congress of Hygiene, São Paulo, 1948. In it the author sums up a large amount of work [most of which has been reviewed in this *Bulletin*] dating from about the time when SHANNON, WHITMAN and FRANCA isolated the virus from *Haemagogus capricornis*, *Aedes leucocelaenus* and a group of Sabethine mosquitoes, all caught wild in the forest. In the region where these captures were made, *Haemagogus spegazzini* is commoner than *H. capricornis*, and the importance of *H. spegazzini* as a vector has been confirmed by LAEMMERT *et al* [this *Bulletin*, 1947, v 44, 414]. The two species, which at one time were regarded as the same, can be distinguished by the terminalia of the males, but this is not very helpful in field work [see also this *Bulletin*, 1945, v 42, 609, footnote].

The author discusses the animal reservoir of yellow fever, and gives spot-maps showing the distribution of human cases (1939-48), the places where immune bodies have been detected in various genera of Primates, and the places where various species of *Haemagogus* and *Aedes leucocelaenus* have been found. He notes that marking experiments have shown that *H. spegazzini* and *Aedes leucocelaenus* can fly 10 and 6 kilometres respectively from the point of liberation.

Charles Wilcocks

RABIES

WILLIAMS R. B. *Epidemic of Rabies in Interior Alaska 1945-47* *Canad. J. Comp. Med.* 1949 June v 13 No 6 176-183 1 map.

In the present article proof is adduced that rabies is widespread over Interior Alaska and reached epidemic proportions during 1945-47. It emerges that the causative virus is firmly established in the territory's wildlife population and that rabies in the fox constitutes a major problem in control. Thus in Alaska the wild animals, especially the fox are a reservoir of infection for dogs and other species, including man.

During the 1945-47 epidemic it was possible by clinical and laboratory examination to demonstrate the disease in 7 foxes, 3 dogs and 1 wolf. No deaths from rabies among human beings were recorded—a circumstance which may apart from the obvious difficulty of collecting accurate information in such a territory be explained by the availability of anti-rabies treatment and the heavier and the more protective nature of the wool and fur clothing worn in these latitudes.

G. Stuart

VERLINDE J. D. & KRETZ A. Failure to cultivate Rabies Virus in Vitro *Antonie van Leeuwenhoek J. Microbiol. & Sewol.* 1949 v 15 No 1 71-8

"Report of the unsuccessful cultivation of rabies fixed virus in a cell free medium consisting of steamed sheep-brain extract glycine peptone and a number of accessory factors (tryptophan, ascorbic, nicotinic acid, amide pyridoxine hydrochloride, sodium pantothenate and lactoflavin). After 1 and 48 hours incubation at 37°C under aerobic conditions, the virus had completely lost its virulence and did not induce immunity to reinoculation with active virus.

WIKK R. C. & ECKER E. E. Time of Appearance of Antibodies to Brain in the Human receiving Anti-Rabies Vaccine. *Proc. Soc. Exp. Biol. & Med.* 1949 Apr v 70 No. 4 734-7 7 figs. 13 refs.

For many years it has been known that a disseminated type of encephalomyelitis can be produced in experimental animals by the injection of either homologous or heterologous brain tissue and that the lesion found in this condition closely resembles those present in human demyelinating diseases including the encephalomyelitis which follows anti-rabies treatment. Consequently the possibility has been suggested that re-immunization to brain tissue may be the factor responsible for the production of these diseases and, in particular, of the encephalomyelitis occasionally observed to complicate the administration of anti-rabies vaccine inasmuch as in the latter the injection of heterologous brain tissue parallels in many respects the experimental procedure followed with the experimental animals.

It seemed of interest to the authors therefore to ascertain in a preliminary study if bitten persons treated with simple plasma killed rabbit brain virus vaccine whether or not such treatment did in fact lead to the development of anti-brain antibodies in the patient sera. To this end antigens prepared from the white matter of fresh human brain were employed for (1) the immunization of rabbits to determine the antigenicity of the brain extract used and (2) the titration of the sera of the five patients receiving the anti-rabies vaccine. As regards (1) results confirmed that antibodies to brain tissue are produced in the rabbit by the intracerebral injection of foreign brain substance. As regards (2) the findings may be summarized as follows:

In three patients, to whom the routine 14 daily injections had been given, the sera showed a negative complement-fixation reaction until the 15th to 18th day, when antibodies to the brain antigen made their appearance. In the fourth patient who, without personal history of allergy, had been compelled on account of excessive local reactions to discontinue treatment after the fifth injection, a condition necessitating admission to hospital and diagnosed provisionally as "possible encephalitis following anti-rabies treatment" developed six days after the first injection and continued until his recovery and discharge from hospital 14 days later. In this case samples of sera, obtained on the 9th and 12th day after the beginning of symptoms, showed a high titre of complement fixation when compared with the sera taken from the other cases investigated. In the fifth patient no anti-brain antibodies occurring after treatment with anti-rabies vaccine were at any time demonstrable.

Results of the authors' present investigation adduce evidence that antibodies to human brain are produced in patients receiving the Semple anti-rabies vaccine. The fourth case suggests the possibility that a markedly increased anti-brain antibody titre may occur in those patients who develop an encephalitis after this treatment.

PLAGUE

P'AN, H. S. TCHAN, Y. T. & POCHON, J. Etude cytologique de *Pasteurella pestis* soumis à l'influence du bactériophage spécifique. I. Modifications morphologiques de l'appareil nucléaire. [A Cytological Study of the Effect of Specific Bacteriophage on *Past. pestis*. I. Morphological Changes in the Nuclear Apparatus.] *Ann. Inst. Pasteur* 1949, May, v. 76, No. 5, 468-70, 4 figs.

The authors had previously demonstrated the presence of nuclear material in *Past. pestis* by the technique of ROBINOW. They described two nuclear granules in each resting cell which fused to form a single dumb-bell-shaped structure during the process of bacterial division. Fragmentation of this structure into four chromatin granules preceded protoplasmic fission, so that each daughter cell had two nuclear granules as in the original resting cell.

In organisms exposed to the action of a specific phage, the normal process of nuclear division did not take place. Both the bacterial bodies and the nuclear material showed marked swelling. The two nuclear granules fused together to form thick chromatin rods which became elongated and filamentous with further increase in size of the bacterial body. After four to five hours' exposure to phage action, the nuclear material gradually became indistinguishable with the final disruption of the organism. The authors contrast this sequence of events with that seen in susceptible organisms exposed to the action of penicillin in which nuclear division was unimpaired but fission did not take place, so that giant bacterial forms with multiple nuclei were eventually seen.

CHOLERA

KAMAL A. M., with G. A. MESSIR & Z. KOLTA. Experiences in the Recent Cholera Epidemic in Egypt. Reprinted from *J. Egyptian Pub. Health Ass.* 1948, 185-96. 3 charts (1 folding). [13 refs.]

This paper presents the personal conclusions of the authors on the observations made during the outbreak of cholera in Egypt, most of which have already been published.

GRANT, M. H. & MURRAY, M. V. Clinical and Biochemical Studies in Cholera and the Rationale of Treatment. *Trans. Roy Soc Trop Med & Hyg* 1949 July v 43 No. 1 81-88. [14 refs.]

In discussing the clinical and biochemical observations made on cases of cholera during the Egyptian epidemic of 1947 the author presents his findings on the losses incurred and the deductions made as to the suitable methods of treatment for their rectification. The findings are in general, in accordance with usual experience.

Dehydration.—Clinical severity was found to be in direct proportion to clinical dehydration and to the number of evacuations that had occurred. It was related to both water and electrolyte loss and not to either alone. The water loss is considered to be more important as no special clinical manifestations could be ascribed to salt depletion alone. The author considers that the use of isotonic rather than hypertonic saline for transfusion is indicated. The specific gravity of the plasma is the best single indicator of the degree of dehydration and a guide to calculating the amount of fluid needed for correction.

Blood and urine chlorides.—Blood chloride was found to be raised in all cases. In 16 cases the figure ranged from 520 to 710 mgm. per cent. The higher figures were associated with a severer grade of dehydration and indicated the necessity for energetic treatment.

It was considered, however that the estimation of plasma chlorides is fallacious as an indicator of the total loss of chlorides because of the tendency to hypertonicity in the diminished extracellular fluid. Urine chlorides were low in all cases on admission and, taking into account the small amount of urine passed, the total excretion indicated marked salt depletion. No correlation was found between urine and blood chlorides—the urine chloride levels form a better measure of the total chloride loss and a guide to salt therapy.

Potassium loss.—Disturbance of electrolyte balance occurs in cholera and a diminution of blood potassium was found in the majority of cases examined. This did not bear any relationship to clinical severity and no special clinical manifestations were attributed to it. It is suggested that the lower levels found may have been due to loss in the excreta in the absence of intake. Investigations on the point are indicated.

Plasma proteins.—About two-thirds of the cases examined showed hyperproteinuria and one-third showed hypoproteinuria. The differences are attributed to the balance of the factors of blood concentration and protein loss. Possible factors producing protein loss are discussed. The author considers that cases showing hypoproteinuria should be given plasma transfusion and that the indication for this would be the figure of the specific gravity of the plasma. (Other workers in Egypt have considered that plasma transfusion is contraindicated in cholera.)

Azoetemia.—Azoetemia was demonstrated in two-thirds of the cases studied. It has no relation to clinical severity. It disappeared in all but three cases under treatment. Although it is mainly related to dehydration and circulatory failure it has no relation to the degree of blood concentration, or hypochloroemia. A renal factor of toxic nature in the production of azoetemia is suggested by the present work.

The mechanism, effects and prognostic significance of anuria and the importance of its rapid correction are discussed.

Treatment.—Detailed recommendations for treatment are presented. Isotonic solution or preferably Ringer's solution, is advised for transfusion to begin with, until urine chlorides reach 5 grammes per litre or more and, after that, the same solution made hypotonic by the addition of an equal amount of 5 per cent. glucose solution. The use of sodium lactate is recommended for

amoebiasis may occur in epidemic form even in the temperate zone. It may also be pointed out that carrier rates are high in the Northern States such as Minnesota and Pennsylvania and constitute a potential source of danger even in the temperate zone. On the other hand some epidemiologists have not yet fully accepted the view that amoebiasis is water-borne and consider that the Chicago epidemic was so unusual that it should be considered as an exception rather than the rule.

Observations show that many people may be infected with *E. histolytica* and yet show no symptoms and have no history of dysentery. It has therefore been suggested recently that the Chicago epidemic might have been an outbreak of bacillary dysentery among a population with a high carrier rate of *E. histolytica*.

Clinically the cases of amoebic dysentery may be divided into two groups: primary and secondary dysentery. The primary cases are those that develop dysentery after the direct ingestion of infective material. The secondary cases are those that have been carriers for months or even years and develop amoebic dysentery upon the introduction of certain secondary factors.

The incubation period of the naturally infected cases may be as short as nine days but in the secondary cases the period is difficult to assess. The authors of 16 selected cases from the Chicago epidemic gave the following incubation periods:—

less than 11 days	23 per cent
between 11 and 20 days	23
between 21 and 30 days	23
between 31 and 120 days	3

On account of the relatively long incubation period in the majority of cases the extent of the epidemic was not realized during the outbreak because there were only 15 cases which were connected with the two hotels involved and reported to the Chicago Board of Health. The size of the epidemic was only disclosed by the questionnaire survey made later.

Amoebic cysts may survive in water or sewage for a few days to almost three months depending on the temperature of the suspending medium. The cysts are only slightly heavier than water so that one cannot depend on storage of water or sewage for removal of cysts unless a long period is allowed for sedimentation. Perhaps one of the best methods of removing amoebic cysts is by flocculation and filtration through pressure filters, 94 per cent being removed. If chlorination is the only method available for the destruction of cysts in water then superchlorination or breakpoint chlorination must be employed.

For emergency treatment of water to destroy cysts, up to hypochlorination at pH 5.0 to 6.0 followed by dechlorination or treatment with elemental iodine to give a residual of about 4 to 5 ppm in 10 minutes at pH 5.4 to 6.0 would be satisfactory.

CODELEONTINI F. Studio statistico sulle parassitosi intestinali nello Sleso.
(Intestinal Parasitism in Sleso. *Atti M. S. Italiana* 1919 July 4 N. 7
174-8, 1 chart. English summary (2 lines).)

In Addis Ababa the Imperial Ethiopian Medical Research Institute has a good laboratory under Professor Guagunt. In this paper the author reports on the results of the examination of 7,600 samples of faeces in the six years July 1941-June 1947 inclusive. The samples were the second or third results examined in fresh stool after saline purgation. Of the total, 4,732 (60.1 per cent.) were positive for some parasite or other. 424 were positive among 1,607 samples from Europeans (26.3 per cent.) and 4,308 among 6,995

Ethiopians (68.7). The parasite most commonly found was *Entamoeba histolytica* (1,611), *E. coli* was next (1,243), *Chilomastix mesnili* came third, but a long way behind (357), and then, in order, *Trichomonas* (288), *Trichuris* (280) [mentioned as *Trichocephalus*, but further down in the same list is *Trichuris trichiura* 77], *Giardia* (260), of the cestodes *Taenia saginata* was found in 191, but *T. solium* once only and that in a European, *Ascaris lumbricoides* was not common (136) and *Ancylostoma* in 97 only. *Schistosoma* [species not mentioned] was seen once only, in an Egyptian immigrant.

MONTERO, E. & URIBE, V. Correlación endoscópica, parasitológica y serológica en el diagnóstico de la amebiasis (Comunicación preliminar) [Correlation of Endoscopy and Parasitological and Serological Examinations in the Diagnosis of Amoebic Infection] *Rev. Med. Chile* 1949, Mar., v 77, No 3, 143-8 [38 refs.]

In more than 70 per cent of fatal cases of amoebic dysentery lesions are found in the rectum and sigmoid, and MANSON-BAHR has shown that in 90 per cent of 258 patients with parasitological evidence of intestinal amoebiasis such lesions are visible by endoscopy [this *Bulletin*, 1942, v 39, 29], thus, in 10 per cent (some authors give a much higher figure), in spite of the infection, no local lesions are found by endoscopy, the higher levels of the colon or the caecum being attacked. There is no need to stress the frequency with which the *Entamoeba* is not found by direct faecal examination. The results of complement fixation tests vary greatly in the hands of different authors and according to the nature of the antigen used.

In the present investigation, the authors have carried out all three methods in 70 patients: 17 with acute amoebic dysentery, 27 with chronic intestinal amoebiasis, but no dysentery, 10 with amoebic hepatitis or liver abscess, and 16 with non-amoebic conditions as controls, among them 3 normal subjects, 5 with ulcerative colitis and 4 with chronic diarrhoea. The lesions as seen by endoscopy the authors divide into three grades: I Small crateriform depressions, 1-3 mm in diameter and in groups, seen by oblique illumination; II Superficial erosions, 3-5 mm in diameter, with slight bleeding; III Typical ulcers and submucous abscesses. The parasitological examination was made of material taken with a pipette and examined at once fresh or in iodine solution, or, if the material was sufficient, concentrated by the centrifugation-floatation method with sulphate of zinc [this *Bulletin*, 1939, v 36, 144, 1940, v 37, 62]. Complement fixation was carried out with the Bozecevic, Hoyem and Walston technique as modified by REES *et al.* [this *Bulletin*, 1943, v 40, 456].

The results are very interesting and instructive. Of the 17 with acute amoebic dysentery endoscopy showed 5 of grade II and 12 of grade III, 13 were positive by direct examination for protozoa, 13 gave a positive complement fixation. Of the 27 with chronic amoebiasis, by endoscopy 17 were grade I, 9 grade II and 1 grade III, 9 only showed protozoa by direct examination and only 2 gave a positive fixation of complement. Next, the 10 with amoebic hepatitis: endoscopy showed 4 grade I, 2 grade II and 1 grade III, the other 3 showed no local lesion in the rectum or sigmoid, 5 were positive parasitologically and 8 gave a positive complement fixation. Of the 16 controls none was positive either parasitologically or by complement fixation tests.

Endoscopic examination thus proved the best, especially for chronic cases without dysentery, while complement fixation was of special value in hepatic conditions secondary to amoebiasis of the intestine, where the sigmoidoscope reveals no lesions.

MARGUEZ R. J. Em torno da sintomatologia da amebíase crônica. (On the Symptomatology of Chronic Amebiasis.) *Med Cirurg Farmacia*. Rio de Janeiro. 1949 Feb.-Mar. Nos. 134/135 101-8. [18 refs.]

Now that infection with *Entamoeba histolytica* is no longer almost exclusively tropical, this paper is very salutary for those practising in non-tropical countries and where those who have lived in the tropics have settled elsewhere. The author shows, with illustrative cases, that symptoms of a somewhat vague character such as headache, general pains, loss of appetite, general weakness and "nervousness," palpitation, formication, backache, giddiness, cold and sweaty hands, irritability, "liverishness" and many others may be due to at all events associated with, *E. histolytica* infection and clear up when the infection is specifically treated. To some among the patients mentioned vitamins, liver extract and all sorts of nostrums had been given: one had had his appendix removed without benefit. [There is much to be said in favour of the routine examination of the faeces of any patient who gives a history of residence abroad whatever his symptoms, and the laugh is not always on the side of those who taunt the tropical practitioner with being one of those "Who never his see sees. Until he sees faeces"] H. Harold Scott

TURNBULL, G. C. & COOLEY, J. C. The Clinical Significance of a High Right Diaphragm in the Diagnosis of Amebiasis and Amebic Hepatitis. *Med Times*. New York. 1949 Aug. v. 77 No. 8, 343-7 1 fig.

This paper contains nothing original, but its purpose is to direct attention to the fact that in (some) cases of amoebic hepatitis and amoebic liver abscess the right cupola of the diaphragm is raised (and it might be added, fixed). After appropriate specific treatment it becomes progressively less so. Five illustrative cases are cited. [It is stated that amoebic liver involvement "is usually secondary to intestinal amoebiasis" but surely it is always so, again in the report of case 5 biopsy of a rectal stricture yielded "*Entamoeba histolytica* cysts in the throes," a most improbable finding.]

ARMSTRONG, W. A Case of Cutaneous Amebiasis. *Trans. Roy. Soc. Trop. Med. & Hyg.* 1949 July v. 43 No. 1 79-80 1 fig.

The author has seen two cutaneous lesions in the New Hebrides which appeared to be due to amoebiasis (presumably *E. histolytica*) and one of these is described and illustrated by a photograph.

The patient came to hospital in 1917 with a course discharging, papillomatous type of fungating mass on the scrotum. This had been present for about three years without treatment. The discharge was rich in amoebae.

Emetine 1 gram daily and a local dressing of 1 per cent. carbarsone solution caused the discharge to cease within three or four days after which the carbarsone dressings were replaced by a paint of salicylic acid in tinct. benz. co. Emetine was continued for ten days. The paint was little effective in reducing the warty mass, but glacial acetic acid rapidly cleared the area. There had been no recurrence by May 1948. H. J. O'D. Burke-Gaffney

SWARTZWELDER, J. C. & MCGILL, H. C. Jr. Intestinal Amebiasis complicated by Abscess of the Brain. Report of a Case without Hepatic or Pulmonary Involvement. *Rev. A. de Med. Trop. Parasit.* 1949 Mar-Apr. v. 8, Nos. 3-4 77-9 2 figs. 10 refs.

"*Entamoeba histolytica* trophozoites were cultured from brain abscess material obtained at autopsy from a 45 year old male with amoebic colitis.

A remarkable feature was the absence of amebic lesions of the liver and the lung. This case represents the fifth in a series of brain abscess of amebic etiology without involvement of the liver and the lungs."

RAWKINS, M D & KONSTAM, G L S Complete Heart-Block associated with Amoebic Hepatitis Normal Rhythm restored with Emetine *Lancet* 1949, July 23, 152-3, 5 figs

Heart block in association with amoebiasis is a rarity, only three references to it have been found in the literature of the last 20 years. In these cases auriculo-ventricular dissociation occurred during periods of acute dysentery, the heart condition in two of them improved as a result of emetine treatment but the third patient, a child of five suffering from malnutrition, died. The present record is of a returned British officer, aged 28, who had suffered periodic diarrhoea since service in the Western Desert six years previously. He complained of attacks of giddiness and faintness of brief duration which recurred several times daily, during these the heart seemed to miss beats, and there was lower sternal discomfort and pain in the shoulders. The patient was in quite good condition, the pulse rate was 40 and regular, it rose to 60 on exercise, the liver dullness extended to the fourth space in the mid-axillary line. Screening showed the right dome of the diaphragm to be raised and fixed, its outline was blurred, and there was mottling of the base of the right lung, and this extended to the right root region. The condition was considered to be an amoebic hepatitis with inflammatory changes in the neighbouring lung, though no parasites were found on repeated stool examination, sigmoidoscopy revealed no abnormality, the leucocyte count was 8,000 per cmm. [and there was no pyrexia]

Frequent daily Stokes-Adams attacks occurred, with asystole for three to four seconds, a cardiogram showed complete heart-block, with an auricular rate of 88 and ventricular of 31 per minute, the ventricular rate was slightly irregular. X-rays showed the transverse diameter of the heart to be increased both to the left and to the right, the left auricle was not enlarged.

Daily intramuscular injections of 1 grain of emetine caused the chest pain to disappear and the pulse rate to rise to 80 by the third day, but there were still extra systoles at every third or fourth beat. The heart-block and the Stokes-Adams attacks ceased after the third day of emetine treatment. On completion of the course of emetine (11 grains) the rhythm was normal and the sinus rate 40, with P-R interval 0.2 seconds. By this time there was free movement of the diaphragm, which was normal in level and contour, the heart was more vertical and its contour normal. A cardiogram one month after beginning treatment showed sinus bradycardia with a rate of 45, the P-R interval was 0.24 second. In another three weeks the sinus rate was 70, with a normal rhythm and a P-R interval of 0.2 second, there were no extra-systoles. The heart-block in this case the authors think possibly to have been due either to toxæmia or to a metastatic amoebic infection, in view of the rapid response to specific treatment they favour the latter explanation.

PARMER, L G & COTTRILL, C W Distribution of Emetine in Tissues *J Lab & Clin Med* 1949, June, v 34, No 6, 818-21

This report deals with the distribution of emetine in the tissues of rabbits after single intramuscular injection of 6 mgm per kilo of the hydrochloride in aqueous solution. Fifty-seven animals were used and were killed at intervals of from half an hour to 64 days after injection, for determination of the amount of alkaloid present in various organs. Similar determinations have recently been made by GIMBLE *et al* [this *Bulletin*, 1949, v 46, 467]. The method of estimation employed was based on that of BRODIE *et al* [this *Bulletin*,

It had been suggested previously that the difference in effect of emetine in hepatic and intestinal amoebiasis was due to the differences in concentration of drug in the various organs (PARMER, this Bulletin 1949, v 45 1034) but this view does not seem to be borne out by the present results. The maximum concentration of emetine was generally reached in tissues within 24 hours of administration and after a further similar period the level declined. Some organs were free of emetine within two weeks, in others it persisted a little longer and was detectable for some further weeks in the spleen. Although the concentration in contractile tissues was low these organs appear to be most affected by the drug and it is suggested that their metabolism of glycogen is interfered with. It is still not clear how the drug exerts its effect on *E. histolytica*. J. D. Fulton

THOMSON P. E. & LILLICREY Betty L. Chemotherapy of Experimental *Endamoeba histolytica* Infection in Dogs. Amer. J. Trop. Med. 1949 May v 29 No. 3 323-30 3 figs. (23 refs.)

The need for a suitable host in chemotherapeutic studies of experimental amoebiasis is still apparent. The present authors used dogs aged 6 to 12 months after examination to exclude natural amoebic infection (which was not found) and after treatment with tetrachlorethylene to free them from helminthic infections. The animals were kept in individual cages on an essentially fish diet which was regarded as of importance in maintaining an acute or subacute infection [see FAUST *et al.* this Bulletin 1935 v 12, 777]. They were readily susceptible to infections with *E. histolytica* maintained in culture or passaged from dog to dog by means of a rectal catheter which extended as far as the ileocecal valve and the mortality among infected animals was low. Several million amoebae were given in each inoculum. To obtain faecal samples for examination colonic irrigation was employed. Since only 71 animals were used for evaluating 10 compounds the numbers in each group were necessarily small, sometimes only one dog was used. The authors in spite of some obvious disadvantages of such a large host as the dog, consider that animal to be suitable for chemotherapeutic tests because it can readily be infected and acquires an acute or subacute infection lasting for several months with resultant ulcers and shallow ulceration without infection of other organs. From the results of treatment with emetine, carbamezone, chinolon and diodoquin the correlation between the responses obtained in canine and human amoebiasis was considered satisfactory. The three latter were curative but not emetine, amonquin or chloroquine (both the latter being 4-aminoquinolines). (Chloroquine has recently been reported as effective in human amoebiasis see C. A. this Bulletin 1948, v 45 430 also MARROW BAKER, *ibid.* 1949 v 46 744.) Antibacterial agents including penicillin, streptomycin, sulphadiazine and succinylsulphathiazole proved ineffective in treatment and this suggested that the amoebae rather than the bacteria present were responsible for the lesions encountered. J. D. Fulton

BARRETO J. G. & GUTIERREZ ESTIVILL E. Absceso hepático amibiano curado con cloroquina. Amoebic Abscess of the Liver cured by Chloroquine. Rev. And. M. L. Trop. y Parasit. 1949 Mar-Apr v 5 No. 3 431-7 3 figs. (31 refs.; English summary)

A very interesting case of hepatic abscess is reported in detail in a boy of 17. The physical signs were apparently typical, but an exploratory puncture

yielded greenish-yellow pus in which no trophozoites of *E histolytica* could be demonstrated. The faeces were also negative and there was only a slight leucocytosis (9,800 per cmm).

During the course of open operation thick yellow gelatinous pus was revealed in which also no *E histolytica* individuals could be seen, though, on culture, staphylococci and streptococci were isolated. From the seventh day after the operation increasingly numerous active amoebae (of which figures are given) were seen moving about in the pus. During this interval the patient had been under continuous treatment with streptomycin as well as penicillin. On the eleventh day this treatment was discontinued and chloroquine diphosphate (Tanakan) by mouth instituted (12.5 gm in 26 days) without the supervention of any toxic symptoms. Five days after chloroquine treatment was started the amoebae had disappeared from the pus. On the fourteenth day of the chloroquine course the operation wound had healed satisfactorily. The condition of the patient was excellent and he had put on 31 lb in weight in 2½ months after the operation date. It is therefore concluded that chloroquine cures hepatic amoebiasis. It is clearly stated that no emetine was administered.

In a footnote, Tanakan is stated to be "chloroquine quinoline diphosphate", each tablet containing 0.25 gm which is equivalent to 0.155 gm of the base. It also contains starch (0.07 gm) and colloidal Kaolin (0.45 gm).

The first number of the ninth volume of *Médecine Tropicale* is devoted to three reports on the use of conessine in the treatment of amoebiasis, and to an extensive bibliography on the drug. Since the French workers at Dakar [this *Bulletin*, 1948, v 45, 905] redirected attention to the therapeutic efficiency in the treatment of amoebiasis of the alkaloids of *Holarrhena africana*, and in particular of conessine, several other French workers have reported most favourably on it [this *Bulletin*, 1948, v 45, 1086, 1949, v 46, 365, 469]. The first two of the three papers summarized below consist of reports on the treatment of patients suffering from various forms of amoebiasis, in France and in Cochinchina, with "Roquessine", a proprietary preparation of conessine hydrochloride put up in cachets each containing 0.1 gm of the compound for oral administration. The third paper contains an account of the action of conessine *in vitro* as compared with that of emetine, there are some studies on its excretion in the faeces and the urine, and its relative concentrations in the fluid and cellular contents of the blood have been estimated. In an appendix there are lists of references in the literature, arranged in chronological sequence, to the plant and its derivatives.

These papers contain much detail which it is impossible to summarise they should be consulted in the original by those interested.

1. Of forty patients suffering from amoebiasis, contracted chiefly in Indo-China, thirty-eight withstood a full course of treatment with coneosine at the Michel Lévy military hospital at Marseilles during 1948. Two other patients began the drug, which had to be stopped on account of the development of serious toxic manifestations. The findings and progress in each case are recorded in detail. Most of these persons had previously had repeated treatments with the accepted drugs many of them were suffering from a chronic dysentery which proved refractory to the usual therapy.

With the use of Blanc's classification the cases completing treatment could be relegated to one of the following clinical types of amoebiasis —

Type 1 — Acute intestinal relapse (6 patients)

Type 2 — Chronic intestinal amoebiasis

(a) with diarrhoea (6 patients)

(b) with alternating diarrhoea and constipation (3 patients)

Type 3. — True chronic amoebic dysentery (18 patients)

Type 4 — Hepatic amoebiasis (5 patients).

Type 1 cases (6) were given at least 4 gm. of "Rorpesalbe" orally over a period of ten days. Acute symptoms usually subsided by the second or third days of treatment the stools became formed by the fourth, and amoebae disappeared concurrently. Cysts are also said to have vanished, but subsequently reappeared intermittently. Sigmoidoscopy showed healing of ulceration in two of the cases, and substantial diminution in ulceration in another three. In all the general physical condition rapidly improved.

Type 2 (a) cases (6) in which emetine is stated to be of little value showed an equally rapid response to coneosine in doses of 4-8 gm. and upwards over 13 or more days. Relapses, however subsequently occurred.

(From one of the six patients listed no amoebae or cysts were recovered to substantiate the diagnosis which was based on a past history of dysentery. This patient had ascariasis, and did not benefit from treatment with santhoin or chenopodium or with sulphaguanidine emetine or coneosine.)

Type 2 (b) cases (3) also rapidly improved with coneosine (11 gm.) but colonic dysfunction continued, as in the preceding type.

[From one of the three patients listed no parasites other than *Giardia* were recovered another was passing cysts only in spite of the evacuation of five to six loose motions each 24 hours.]

Type 3 cases (18) all of whom had been suffering from continuous acute dysentery had previously failed to benefit from the classical treatments including emetine penicillin and sulphaguanidine. In all of them symptoms vanished during the second day of treatment the stools from 12 of them were formed by the sixth day but in three others they were occasionally loose and in the remaining three they continued constantly so. Amoebae had disappeared from the stools by the fourth day but in five cases later recurred. In seven cases cysts appeared transiently about the 10th to 14th day and these from their appearance were thought to be non-viable they then vanished from the stools. Ulceration of the bowel showed healing by the 30th day in nine patients in four others additional coneosine treatment eventually produced healing but in the remaining case examined by sigmoidoscopy the ulceration persisted. Abdominal physical signs had vanished after treatment in four cases diminished in ten but persisted in the remaining four. The general health and condition in all was restored in such a striking manner as to suggest a "cure" in some of them. In three of four cases where diarrhoea recurred

soon after treatment a second course of conessine after a couple of months produced the desired effect, but the fourth patient required a third course of conessine to achieve this

Type 4 cases (5) with pre-suppurative hepatitis or, in one case, recrudescence after drainage of a liver abscess with extension to the right lung, all responded in a "spectacular" manner to conessine treatment and symptoms and signs vanished

After detailing the clinical response of the various types of amoebiasis to conessine treatment the authors turn their attention to the optimum dosage, and to the toxic manifestations produced by the drug. The pharmacology of conessine has already been examined by English and Indian workers, and more recently it has been re-examined by the French workers, in particular at Dakar [see this *Bulletin*, 1948, v 45, 905, 1086, 1949, v 46, 365, 469]. The authors gave five doses each of 0.1 gm of conessine hydrochloride in cachets ("Roquessine") daily for five days, and immediately followed this by three doses of 0.1 gm daily until the necessary total dosage was reached. This total ranged from 2.5 gm to 6.1 gm in different cases, the average was 4 gm for a case of acute intestinal relapse, 4.8 gm for a case of chronic intestinal amoebiasis with diarrhoea, 4.1 gm for a similar case with alternating diarrhoea and constipation, 5.0 gm for one of true chronic amoebic dysentery, and 4.6 gm for one of hepatic amoebiasis. Five patients underwent a second course of treatment between 30 and 113 days of completion of the first course, and one patient had three courses of conessine treatment, totalling 14.5 gm of the drug, in 112 days. Tests of the urine with Tanret's reagent showed that the excretion of the drug varied in a manner unrelated to the daily or to the total dosage of the drug.

"Roquessine" by the mouth caused no intestinal upset of significance, but gave rise to a bitter taste in the mouth, it commonly led to difficulty in getting to sleep, and nightmares. In some cases motor and psychic disturbances developed, and in two instances these were serious and in one of these mania developed which required prolonged shock treatment, this patient had a psychopathic personal and family history. Buzzing in the ears, giddiness, and temporal headache were encountered, and these often were associated with tremors of the extremities, and of the tongue, these did not interfere with normal activities and disappeared during complete relaxation. Persons of unstable psychological make-up suffered most from these troubles, and Gardenal at bedtime usually, but not invariably, resolved them, they were most evident early in treatment, and in any event spontaneously vanished a few days after its completion. The blood pressure was not affected by conessine, but in about half the cases treated there was some change in the red cell count and haemoglobin content of the blood. In four instances the values for these were raised, in seven reduced (in three markedly so), but no abnormal red cells were seen, liver therapy rapidly restored the counts to normal. Minor variations were observed in the total leucocyte counts and differential counts, but no abnormal white cells were seen.

The authors conclude that conessine is an excellent specific therapeutic remedy in all forms of amoebiasis, and it produces remarkable relief of the manifestations directly attributable to the parasite but, like other amoebicidal drugs, it fails to correct the sequelae of intestinal amoebiasis, in particular colonic dysfunction.

11 During July 1948 in Saigon, Cochinchina, 135 patients of whom 129 were Europeans, were treated with "Roquessine", 105 others were similarly treated during August and September. These patients included sufferers from amoebiasis in all its forms. Kurchi bismuth iodide [a preparation of *Holarrhena*, also known as *Kurchi*] in 5-grain tablets had become available in

between the fourth and ninth days and amoebae vanished from the stools in 48 hours together with co-existent flagellates, but cysts usually persisted to the end of treatment

In 15 acute cases of relapsing intestinal amoebiasis (with from two to seven relapses), all of whom had received previous emetine treatment, and some of them penicillin and sulphaguanidine, parasites disappeared in two or three days and the stools became normal usually between the third and sixth days, symptoms disappeared and the appetite, general condition, and in some cases the weights of the patients were restored to normal by the end of treatment. So successful was the treatment that men were retained in the East whose condition before treatment seemed to necessitate repatriation

Two cases of "true chronic amoebic dysentery" were treated, one of which had proved refractory to emetine treatment, and the other to emetine-penicillin-sulphaguanidine and to arsenicals, in the former a course of "Roquessine" caused the disappearance of amoebae from the stools and their replacement by cysts in three days, the stools becoming formed by the 17th day. In the second, though the drug caused sympathetic disturbance and insomnia, the abdominal pains disappeared, the appetite was restored and the patient gained weight, but the stools continued loose throughout the ten days' treatment though subsequently they became formed

Twelve cases of chronic amoebiasis with diarrhoea were treated. In only six of these were amoebae present in the stools at the time of treatment, in three they had been found at an earlier date [in the remaining three none had been detected]. In seven of these cases the stools became formed between the 6th and the 27th days, in three cases although the stools remained loose the symptoms and signs abated, in one case, of nearly ten years' duration and repeatedly treated with emetine, no benefit resulted from "Roquessine" treatment, and in yet another also there was no improvement following it

Two cases of chronic amoebiasis with constipation [in one of which no parasites had been found and the history and physical signs were very dubious] were treated with "Roquessine" and both cleared up in a spectacular fashion

In two cases of chronic amoebiasis with alternating constipation and diarrhoea the symptoms disappeared within 15 to 20 days

Three patients suffering from sequelae of amoebiasis were treated with conessine. The first presented a classical picture of sprue [but no evidence of amoebiasis] which had resisted classical sprue treatment, this patient was much improved if not cured, by a course of conessine. Another similar case, but with a history of amoebiasis parasitologically diagnosed in 1926 and treated with emetine in 1947, temporarily benefited from conessine treatment but relapsed. The third, another classical case of sprue, who had had parasitologically diagnosed amoebiasis in 1946 and been treated with emetine, improved with conessine treatment

Twelve cases of pre-suppurative amoebic hepatitis, four without pyrexia, responded immediately to conessine treatment, the symptoms and signs of liver involvement and of acute intestinal amoebiasis rapidly vanishing. In addition a case of pulmonary amoebiasis secondary to liver infection rapidly cleared up with conessine treatment

The author concludes that the therapeutic results obtained in the treatment of the first 135 cases of amoebiasis of all types in Cochin China are comparable to those obtained at Dakar. While the response to treatment varies with the type of case, the aggregate results are good. In early acute amoebiasis they were remarkably good, in relapsing acute amoebiasis they were good but the response was less rapid, in chronic relapsing amoebiasis although the results were encouraging too few cases were treated to arrive at any firm conclusion, though it was evident that conessine can be substituted for emetine in such

cases when the latter proves inadequate. In chronic amoebiasis with diarrhoea the results were inconstant, good results being obtained in only half the cases; in chronic amoebiasis with constipation the results were good; in chronic amoebiasis with alternating constipation and diarrhoea the results were also quite good. In cases of sprue—a sequel of amoebiasis—the results were contradictory. In cases of pre-suppurative hepatitis the results were excellent.

"Roquesure" caused amoebae to vanish from the stools in two to three days but they often persisted in the colon (sigmoidoscopic scrapings); cysts in the stools were unaffected by coeseine treatment. Flagellates were present vanished from the stools, but an *Entamoeba coli* infestation was unaffected by the drug. In view of the persistence of an *E. histolytica* infection in so many cases after coeseine treatment this should be followed by a course of treatment with stovarsol.

As an appendix are recorded briefly the results of treatment of 105 additional cases of various types of amoebiasis. These confirm the provisional conclusions reached above.

iii. Only after thirty years' daily clinical usage and extensive laboratory study, has an adequate estimate of the value of emetine been reached. Though coeseine undoubtedly is of value in amoebiasis, and there have been many optimistic reports on its prolonged studies, both laboratory and clinical, are necessary for its proper assessment. Early impressions gained from the cure of, or improvement in cases of amoebiasis treated with coeseine alone are insufficient.

Amoebae only grow freely in culture media which are in part solid and in part fluid; that most employed consists of a coagulated horse serum slope covered with a mixture of seven parts Ringer solution and one part horse serum, to which is added rice starch. Chemical compounds added to this medium are distributed unequally between the fluid and solid constituents (this was shown by Lakshmi Dobell and Bishop some 20 years ago to be the case with emetine). They found emetine when added to the liquid component of the medium, in some days to be reduced in amount by as much as 80 per cent. As a result they recommended that in assessing the value of speculative compounds with such a medium emetine should be used as a basis for comparison. Composite media have been discarded in favour of liquid media for the examination of drugs, in spite of the inferiority of these in promoting growth of the amoebae. Jones using liquid media, showed amoebae to be 10 to 50 times as susceptible to emetine in an alkaline as in an acid solution. He found that emetine added to a culture immediately before sowing inhibited growth in concentrations of between 1/1 000 000 and 1/5 000 000 in an alkaline medium and between 1/100 000 and 1/500 000 in an acid medium. If however the emetine were added to an established culture of amoebae concentration of 1/50 000 was necessary to kill it in five days (this is "true lethal action"). The figures in the literature for coeseine are less precise but they indicate that coeseine is anything from 4 to 140 times as active as amoebicidal as emetine *in vitro*.

The authors consider that figures for amoebicidal concentration of a drug obtained by using purely liquid media are unduly favourable to the compounds tested, as the amoebae are not growing, under optimum conditions of culture. For this reason they prefer composite solid and fluid media in spite of the uncertainty as to the drug concentration in such media. After trial, a technique for determination of the effective concentration of the added drug in the medium based on that of Macgregor and Laisant was adopted. Briefly this consists of precipitation by an excess of nitro-tungstic acid of the alkaloids in an acid medium and their removal by centrifugation. Titanic chloride is added to the supernatant fluid and the resultant blue colour can be used for a

colorimetric estimation of unaltered silico-tungstic acid in the supernatant fluid, the amount of alkaloid can thus be calculated. Estimations with this technique of known concentrations of the hydrochlorides of conessine or of emetine in aqueous solution proved satisfactory. In sterile liquid culture media there is an apparent loss of the drug which increases with time, and is greater in the case of conessine than in that of emetine, the loss is possibly due to fixation or to destruction of the compounds. In mixed solid and liquid media, on the other hand, though the loss is even greater than in purely fluid media the recoverable amounts of the two alkaloids are about equal.

Two methods of determining the amoebicidal concentrations of conessine and of emetine *in vitro* were used. In the first the drug was added to the tubes immediately before infection, and they were examined after four days, in the second the drug was added to a four-day-old culture of amoebae, and the tubes were examined 24 hours later. Two strains of *Entamoeba histolytica* were employed, the first (Strain P) was obtained from a patient from Réunion, and had been maintained in culture only for a few weeks, the other (Strain M) had been maintained in culture for several years. Three tubes of each dilution of the drug under examination were put up in each experiment, together with controls, the parasites were studied microscopically for their general morphology and motility, and the ratio of dead to living organisms was determined. The results of experiments, with a mixed solid and fluid medium, are summarized in the following table —

Strain	Dilutions causing inhibition of cultures at time of sowing		Dilutions killing 4-day cultures in 24 hours	
	Conessine	Emetine	Conessine	Emetine
Strain P	59 000	240 000	5,300	3,800
	to 71,000	to 300 000	to 7,100	to 4,800
Strain M	45 000	210 000	4,100	2,850
	to 52,000	to 260 000	to 5,350	to 3,450

From these figures it is concluded that Strain M is rather more resistant than Strain P to both drugs. The determined lethal concentrations of emetine added at the time of sowing the medium agree with those reached by previous workers, bearing in mind that at the start the pH of the culture tubes was 7.3 and that this changed to 6.8 in several hours and remained below 7.0, the lethal concentrations of conessine under the same conditions were found to be about four times as high as those of emetine, thus conessine proved only a quarter as effective as emetine when added to cultures of amoebae at the time of sowing. In experiments in which established cultures of amoebae were used, and in which the "true lethal action" of the drugs was revealed, conessine proved slightly more potent than emetine. While it is not possible to draw conclusions as to the therapeutic efficiency of the drugs from these results, it may be remembered that although four times as much conessine is necessary to produce the same effect *in vitro* the therapeutic dosage of conessine at present employed is at least five times as great as that of emetine.

Some studies were made on the elimination of conessine in those treated with a therapeutic dosage of the drug.

Faeces.—A satisfactory technique, basically similar to that already mentioned, was elaborated for the estimation of the alkaloidal content of

faecal suspensions. Analysis of stools from 15 patients undergoing a standard course of treatment with coneosine failed to reveal the presence of the alkaloid in any specimen, even when a sample as large as 10 gm. of stool was examined. The inference is that the drug is destroyed or much more probably absorbed from the intestine in which case it should be recoverable from the urine.

Urine—DUBREUX, TREVORA, TANGUY, ROBIN and KACLET [this Bulletin 1948 v. 45 808] found that up to 140 mgm. of coneosine was excreted in the urine daily by those undergoing treatment for amoebiasis; they found the urinary excretion of the drug to be slow and erratic. The technique for estimation they employed (a nephelometric method with Mayer's reagent) on re-examination gave inconstant results, and so estimations were made of the alkaloidal content of ether extracts of urine with the technique already outlined: this method was found to give consistent and accurate results. Curves are given of the urinary excretion of coneosine by three patients taking 0.5 gm. of the drug daily for six days, and by a volunteer taking 0.5 gm. daily for seven days and then 0.3 gm. daily for six more days. The drug was not found to cause diuresis. In the first three cases the maximum urinary excretion of the drug in 4 hours was 42 mgm. about the fifth day, a figure considerably below that recorded by the above-mentioned workers. On ceasing oral administration of the drug, the excretion in urine rapidly fell, although in one case there was a brief paradoxical rise towards the eighth day; thereafter the excretion diminished until by the 15th day it ceased.

In the fourth subject who was on a more prolonged dosage the curve of excretion was similar and, again, excretion continued for ten days after cessation of the treatment. The gross amount of drug excreted in the urine by any of these patients was less than 10 per cent. of that administered: the balance of the drug was therefore either destroyed or faecal.

It proved impossible to determine the blood levels of coneosine as the amounts were so small. After addition of coneosine to uncoagulated blood and incubation for some hours it was possible to recover all the drug added and this was found to be equally divided between the plasma and the cellular constituents.

McVAY L. V. LAIRD R. L. & SPRUNT D. H. A Preliminary Report of the Successful Treatment of Amoebiasis with Aureomycin. *Science* 1949 June 10 590-91

The treatment of amoebiasis with the drugs currently used is unsatisfactory and involves the risk of toxic reactions. Aureomycin hydrochloride treatment had been noticed to alter the stools and to reduce their content of bacterial flora, so three microscopically proven cases of intestinal infection with *Entamoeba histolytica* were treated with a gross dosage of from 19 gm. to 22.7 gm. of the drug. The blood levels estimated in two of the cases were 8 μ gm. per cent. In all three cases the parasites vanished from the stool within a few days and subsequent examinations by wet and by stained films and by culture on 6 to 14 occasions failed to show a recurrence. Another 11 cases of amoebiasis have similarly since been successfully treated. The amoebae from the first three cases were cultured on Nelson's egg yolk alcoholic extract medium (this Bulletin 1948 v. 45 179) and aureomycin was added to the overlay of soil culture tubes in concentrations of from 0 to 3 mgm. per ml. The tubes were examined 6, 18 and 48 hours later. A concentration above 0.8 mgm. per ml. of aureomycin killed all amoebae in six hours: the majority of the amoebae were killed by 0.1 and by 0.4 mgm. per ml. in 18 hours; no amoebae survived the lowest concentration (0.2 mgm. per ml.) for 48 hours. It is suggested that

the high blood levels reached in aureomycin treatment may render the drug effective in extra-intestinal amoebic infection as well as in cases of purely intestinal infection

CAMBIES Nouvelle méthode de traitement de la dysenterie amibienne et de la lambliaose intestinale [A New Form of Treatment for Amoebic Dysentery and Giardiasis] *Bull Acad Nat Méd* 1949, v 133, Nos 15/16, 348-50

Lambliasis and amoebiasis are commonly found to occur concurrently, both in those infected overseas and in those infected in metropolitan France. Their presence should be suspected in ill-defined cases of intestinal or of gall-bladder upset. The amoebae normally inhabit, in particular, the upper and the lowermost parts of the large intestine. *Giardia* occurs in the duodenum, the ileum, the gall bladder and the liver. The classical treatments for these infections produce inconstant results, and a suitable therapeutic agent would be a non-toxic drug for oral administration which is parasitocidal to both organisms and is concentrated in the liver and excreted in the bile. "Le dérivé disodique de l'acide (3' 5', 3" 5" tétraodo 4' 4" dioxy triphényl-carbinol) carboxylique 2" [the disodium derivative of 3' 3' 5' 5' -tetraodo-4' 4' -dihydroxy-triphenyl carbinol-2" carboxylic acid] appears to fulfil these conditions. Administration of this compound to a total of 12 gm, given in cachets in three doses over a period of 36 hours, to some 300 patients since 1944 has shown it to be effective in eradicating *Giardia* and amoebic infestations, further details are to be published

TORGERSEN, O Balantidium-dysentery [Balantidial Dysentery] *Nordisk Med* 1949, July 29, v 42, No 30, 1271-3, 4 figs

The English summary appended to the paper is as follows —

"A 60-year-old farmer's wife suffered for four months from severe diarrhea. Blood was occasionally detected in the stools, but bacteriologic and serologic examinations were negative. Microscopy of the feces was performed once only, the result being negative. Examinations of the gastric contents revealed achlorhydria. The patient's general condition grew worse, and there appeared signs of severe anemia, and finally a clinical picture resembling pellagra. Autopsy revealed thrombosis of the right femoral vein, pulmonary embolism, fatty degeneration of the liver and of the renal tubules, degenerated myocardial fibers and severe colitis with multiple small ulcers and petechial hemorrhages. Numerous trophozoites of *Balantidium coli* were found in the vicinity of the ulcers. The present case is the fourth reported in Norway."

RELAPSING FEVER AND OTHER SPIROCHAETOSSES

KONITZER, L Relapsing Fever in Ambulatory Practice *Acta Med Orientalia* 1949, Mar-Apr, v 8, Nos 3/4, 48-53 [13 refs]

A review of 26 cases of relapsing fever, all in adult Arabs in Palestine, in which smears of the peripheral blood were positive. With one exception these were thought to be caused by tick infection and the patients gave a history of having slept in the open-air or in caves, the one exception was almost certainly louse-borne.

The author recommends (1) routine examination of thick and thin films stained with Giemsa's stain and (2) careful taking of histories, in all cases of
(1289)

pyrexia. As regards (1) it may be noted that spirochaetes were found on routine examination of thin films in four instances only and that the blood was often positive during apyrexial periods. Penicillin as a therapeutic measure was considered to be too expensive and not practicable in out patient cases. treatment with arsenicals was given in the form of carbarsone by mouth, 0.75 gm. daily for five days or neocarphenamine intravenously (0.01 gm. per kilo body weight) the latter being preferred when atabrin (mepacrine) is given simultaneously. Treatment should be given irrespective of the state of the temperature [The reviewer in his experience of the African type of relapsing fever agrees with this.] Iritis and iridocyclitis were not met with in this series. No mention is made of the type of tick incriminated. C. F. Shotton

BORRIS H. Deux années de recherches sur les spirochètes récurrents à l'Institut Pasteur de Dakar [Two Years of Research on Relapsing Fever Spirochaetes at the Pasteur Institute, Dakar] *Bull. M. d. l'Afrique Occidentale Française* 1948, v 5 No. 1 173-91

A general summary written with the object of presenting a clear picture of the epidemiology of relapsing fever with special reference to work carried out at the Pasteur Institute, Dakar. The small mammals of the district are well known to act as reservoirs of the infection and details are given of the results of one year's examination of 517 rodents and insectivores captured in the town of Dakar during the year 26th September 1946, to 23th September 1947.

Species of mammal	Number examined	Infected		Blood film +	Blood sm. +	Bran. sm. +	Spleen sm. +
		Number	Per cent age				
<i>Cricetomys gambianus</i> us	68	33	80.84	1	18	54	33
<i>Arvicola rufinus</i>	14	11	78.57	4	9	11	9
<i>Rattus alex. alexandri</i>	343	129	34.64	10	57	117	74
<i>Rattus norvegicus</i>	37	8	21.62	1	8	8	6
<i>Rattus rattus</i>	40	6	15.00	0	3	5	6
<i>Urotrichus conchus</i>	1	1	—	0	1	1	1
<i>Taloromys gambianus</i>	1	0	—	0	0	0	0
<i>Mus musculus</i>	6	0	—	0	0	0	0
Hedgehog		2	—	0	1		1
Totals	51	203	39.61	16	85	194	132
				3.1	16.35	37.47	25.78

In view of their habits the two most serious carriers of the infection are considered to be *Cricetomys gambianus* and *Rattus alex. alexandri* us.

During 1946 and 1947 a total of 97 cases of relapsing fever were noted, comprising 58 Europeans and 34 Africans. The great majority of these cases (79) occurred in the European part of the town generally known as Dakar, only 13 cases occurred in the native town Médina. The prevalence of infected rodents in the two districts is very similar and the difference in the rate of human cases would seem to be the result of Dakar having a much more favourable soil for the construction of burrows in which the transmitting host *Ornithodoros erraticus* finds suitable conditions for survival. To combat the disease therefore it is desirable to search for all animal burrows and treat them with chloroform followed by topping up the holes.

The second part of this paper is devoted to a consideration of the transmission of relapsing fever spirochaetes by *Ornithodoros* and by lice

It is well known that *S. hispanica* is transmitted in nature by *Ornithodoros erraticus*. Experiments with lice have given conflicting results but the author obtained transmission in two cases by the inoculation of the contents of infected lice into monkeys and white mice. The spirochaetes, after being ingested by lice, soon become non-motile and disappear, but reappear on the 12th day and persist up to the 24th day after an infective meal. The contents of these lice are infective from the 5th day, indicating the presence of a non-spirochaetal stage of the organism since spirochaetes as such only re-appear on the 12th day. All lice do not become infected when fed on relapsing fever cases, but it is suggested that this is the result of the blood containing too few spirochaetes.

The transmission of *S. duttoni*, var *crocidurae* is next considered and the author gives details of five experiments carried out with this organism. In three cases the spirochaete was transmitted by *Ornithodoros* but not by lice. In two later cases, however, white mice were infected by the inoculation of the contents of lice that had been fed on the blood of a monkey containing numerous spirochaetes and subsequently maintained on normal human blood. The contents of the lice first became positive six days after the infected meal, and remained infective up to the 26th day.

It is evident that the experimental transmission of both *S. hispanica* and *S. duttoni* var *crocidurae* by means of lice is possible, and the problem arises whether such transmission ever occurs in nature. During 1948, the author investigated about 40 cases of louse-borne relapsing fever at Zinder, in the Niger Territory, where an epidemic started in April, 1947. Four young monkeys were successfully infected by intraperitoneal inoculation of blood from patients during the first attack. Newly born white rats and mice were also infected but relapses were never observed and the author was unable to repeat the results of BALTAZARD *et al* [see this *Bulletin*, 1947, v 44, 905] with newly-born rabbits.

Finally the author discusses the epidemiology of louse-borne relapsing fever (*S. recurrentis*). Up to now no animal reservoir has been found, but it is difficult to accept the view that man is the reservoir, and lice can also be excluded, for the infection is not hereditary.

In view of the fact that at least five strains of spirochaetes (*S. hispanica*, *S. microti*, *S. turicatae*, *S. hermsi* and *S. duttoni* var *crocidurae*), normally transmitted by ticks, have been transmitted experimentally by means of lice, it is reasonable to assume that other strains may be equally labile. The long intervals between epidemics of *S. recurrentis* could most easily be explained by assuming the existence of animal reservoirs (small mammals and ticks), but hitherto no tick has been found infected with this strain.

BOREKOV H. Transmission par le pou de *Spirochaeta duttoni* var. *crocidurae*.
[The Transmission of *Spirochaeta duttoni* var. *crocidurae* by the Louse.]
Bull. Soc. Path. Exot. 1949 v 42, No. 3 4 81-3.

The author infected white mice by the inoculation of an emulsion of lice 6 to 14 days after the lice had been fed on a baboon containing in its blood three spirochaetes per microscopic field. These lice had subsequently been fed on a non immune human subject who showed no signs of infection as a result of their bites even though the insects contained infective spirochaetes. [These results confirm those previously recorded by MATTHEWS (*this Bulletin* 1928, v 3 588) and HEISCHE & GARNHAM (*ibid* 1944 v 45 603)] E. Hinde

DELFT L. P. Au sujet de *Spirochaeta microti* Rafy, 1948. [Concerning *Spirochaeta microti* Rafy, 1948.] *Bull. Soc. Path. Exot.* 1949 v 42, No. 5/6, 147-8.

A brief summary of information concerning this spirochaete which was first recorded by RAFY in the blood of a *Meriones* in the neighbourhood of Hemsarek [*this Bulletin* 1947 v 44 87]. ROCHASNIOT subsequently isolated a spirochaete from the blood of *Tatera indica* caught in the same district which seems to be the same species.

The author states that his colleague R. MAUNOURT, during the past two years, has found that 35 per cent. of the *Tatera* in this district are infected, 40.4 per cent. of the *Meriones* and 14.8 per cent. of the hamsters. (See below.) The numerous strains all have the essential characters of *S. microti*. E. Hinde

RAFY A. & MAGNANI, G. R. Recherches sur l'infection expérimentale des rongeurs par *S. microti* Rafy 1948. [Researches on the Experimental Infection of Rodents with *S. microti* Rafy 1948.] *Bull. Soc. Path. Exot.* 1949 v 42, No. 5/6 215-1.

In the neighbourhood of Hemsarek the following species of wild rodents have been found naturally infected with *Spirochaeta microti* —

Rodent	Percentage infected			
	1946	1947	1948	Average
<i>Meriones persicus</i>	—	30	30.7	40.4
<i>Tatera indica</i>	—	20	30	35.0
<i>Neotoma indica</i>	0	35.4	0	1.1
<i>Mus musculus</i>	18.7	0	0	5.5
<i>Cricetus orientalis</i>	19.7	3	0	14.4

Three of these strains, one from *Mus musculus* and the other two from hamsters, were selected, as they showed different degrees of virulence in white rats, that from the mouse (S2) being little pathogenic while one of the hamster strains (S1) was moderately pathogenic and the other (S3) fully virulent.

The strain S1 gave immunity against strains S1 and S2 and slight protection against S3. Strain S2 protected against S2 and S1. Strain S3 conferred protection only against the same strain.

All the ordinary laboratory rodents including rabbits, guinea-pigs, rats, mice and hamsters were found to be susceptible. The white rabbit and guinea-pig showed no obvious signs of infection and usually spirochaetes were not found, yet the blood remained infective to white rats for long periods. Blood was

infective for white rats up to 100 days in the case of the guineapig. The absence of any reaction in adult guineapigs provides an easy method of distinguishing *S. microti* from *S. persica*, in the latter the infection produces definite febrile attacks with spirochaetes in the blood. Young animals were found to be very susceptible to *S. microti* and showed numerous spirochaetes in the blood and in the case of young rabbits sometimes died with signs of haemorrhagic jaundice.

White rats are very susceptible. With a mildly virulent strain, a benign infection is produced (1 spirochaete to 100 fields in the blood) but the virulent strains produce a mortality of 60 to 70 per cent. The incubation period is 1 to 4 days and the animals generally succumb on the fourth to seventh day of the disease with numerous spirochaetes in the blood. Splenectomy renders the white rat much more susceptible and even mildly virulent strains produce fatal infections.

Sheep and dogs were found to be slightly susceptible, showing either a latent or benign infection.

One of the authors became accidentally infected with this spirochaete after a probable incubation period of about 25 days. The infection lasted a month with three febrile attacks (up to 104.2°F) each of 2 to 3 days, separated by intervals of 10 to 12 days. During the febrile attacks, there were rare spirochaetes in the blood, with general symptoms such as headache, pains in the joints, and gastric disturbances. Treatment with neoarsphenamine after the third attack was followed by complete recovery.

Residual infections remain in apparently recovered animals, the brain of the guineapig being still infective 593 days after the original infection.

In nature *S. microti* is usually transmitted by *Ornithodoros erraticus*, in which the infection is hereditary, and more rarely by *O. tholozani*. Experimentally the infection has been transmitted by the bites of *O. lahorensis* and *O. canestrinii*, and by inoculation of the contents of *Argas persicus*. The spirochaete retains its virulence at least 360 days in *O. lahorensis* and 731 days in *O. canestrinii*.

In the discussion following the paper M. COLAS-BELCOUR stated that the spirochaete referred to as *S. laterae* by Rousselot and Rafin-Duvolon, had the same general characters as *S. microti*.

E. Hundle

YAWS

MONTEL, M. L. R. Le pian tertiaire maladie sociale (en Indochine) [Secondary Yaws as a Social Disease in Indo-China] *Bull. Soc. Path. Exot.* 1949, v 42, Nos 5/6, 210-15, 12 figs. on 6 pls.

The term "tertiary yaws", including certain tertiary lesions which encroach upon the secondary stage, is convenient and justified by analogy with the evolution of syphilis. Tertiary yaws is characterized by chronic nodular, ulcerative and gummatous lesions of the skin, bones, periosteum and joints. *Treponema pertenue* is nearly always absent from them. The tertiary stage suggests a sensitization of the body, and histologically the lesions have a tuberculoid character. Not all yaws cases develop tertiary lesions, for in many the condition is cured after the secondary stage, if not serologically at least clinically, and the patient appears normal. This arrest is most frequent in well-nourished and prosperous populations. Where chronic famine prevails, tertiary lesions are frequent and grave.

Lesions of the tertiary stage which encroach on the secondary are (a) palmar and plantar hyperkeratoses of various forms (punctate, fissured, trichophytoid,

desquamating, verrucous or "worm-eaten") which are only the eruption of secondary lesions (raised circular desquamations, pemphigus or fissured pianomes) progressively transformed and organized by hyperkeratosis. (b) Osteo-periosteal lesions of the fingers and toes, a *yaws spina-tendosa* which are often seen in the secondary stage and yet have undoubted characters of tertiary lesions. (The reviewer believes that the characteristic of tertiary lesions is tissue destruction which these borderline lesions probably lack.)

True tertiary yaws lesions begin 7-10 years after the onset of the disease and rarely later. — () Ulcers starting as cutaneous or subcutaneous gummata which break down and spread peripherally. They may involve underlying bones. Sometimes while the lesion is extending, parts of it may be healing. Keloids may be formed. Tenosynovitis and synovitis are not unusual in this stage. (b) Osteo-periosteal and articular lesions with periosteal diaphysal thickening and osteal and subperiosteal gummata with condensation of bone round the lesions, and occasionally obliteration of the medullary canal. Bone lesions may frequently cause sabre tibia. Gummata may ulcerate and give rise to prolonged suppuration and scarring with contractures. The epiphyses and articular parts are less frequently involved than the diaphyses except for osteoporosis. No spontaneous fractures were seen by the author. When tertiary lesions are widespread, profound and sometimes fatal cachexia may be produced. Such widespread lesions are not seen in syphilis. (c) Deformities and contractures resulting from scarring produce permanent disability and atrophy especially of the limbs and are very characteristic of healed tertiary yaws. It is these which have caused the author to call yaws a social disease. Certain lesions may result in patchy depigmentation and atrophy of the skin. (d) Gangosa is not frequent in Indochina, but juxta-articular nodules are. The author has not seen gonodon in Indochina. Leuco-erythroderma and hyperkeratosis of the skin, palms and soles are of the same stage as juxta-articular nodules (but no further description is given in this article).

(The importance of yaws as a cause of suffering in a community is not generally recognized. The misery of tertiary yaws of a few years standing is specially stressed by the author.)

LEPTOSA

NAKAMURA, H. Studies on Cultivation of the Leptocy Bacillus. *Haver Med J* 1949 Mar.-Apr. v 8, No 4 265-8.

This paper is of interest owing to the care taken to avoid the difficulty of determining if the enormous number of lepra bacilli usually introduced into culture media have really multiplied or not. In the present experiment after a second centrifugation of the leprosy material the supernatant fluid which was added to the medium contained only 1.3 bacilli per macroscopic field. The medium contained small percentages of macein 0.4 per cent, soluble starch 0.2-0.4 per cent., glycerin 2.0 per cent, malachal green 0.001 per cent dissolved in distilled water and 5.0 per cent of human or ox serum added immediately before use. The following additional ingredients were also shown to be favourable to growth: phibicol 1% vitamin B₁ 17-4% and vitamin B₂ 17-4% per cc. of culture media. The cultures were incubated at 37°C. for 3 days, at 25°C. for three days, and so on repeatedly. After four or more weeks stained films showed a definite picture of multiplication of the organisms of either human or of rat leprosy in accordance with the inoculum. Subcultures

at six to eight weeks with one drop of a culture produced conglomerations of organisms in a stained film in the case of the rat leprosy bacillus repeatedly and occasionally with the human organism, with the former bacillus rats were successfully inoculated with cultures of the first generation *L Rogers*

VEGAS, M, CONVIT, J & ESPIN, J **Studies on the Reticulum in the Different Types of Leprosy** *Internat J Leprosy* 1948, Oct-Dec, v 16, No 4, 443-50, 8 figs on 2 pls

Reticular fibres can be differentiated from collagen fibres by being profusely anastomosed and they are stained dark brown or black by colloidal silver, while collagen becomes yellowish. Reticulum may be produced from fibroblasts, reticulo-endothelial cells and from blood capillaries. Reticular fibres are arranged about vacuolated cells of Virchow in leprosy. Forty specimens of neural and lepromatous types have been studied with the following results. The reticular formation is a tridimensional network surrounding the granulomatous cells in the inflammatory reaction zones of the simple macular lesions, and grows complex in lepromatous lesions and in tuberculoid lesions and they play an active part in the defensive processes against the leprosy bacillus

L Rogers

CASTAÑE DECOUD, A **Comparative Study of the Nerve Branches of the Skin in Tuberculoid and Lepromatous Leprosy** *Internat J Leprosy* 1948, Oct-Dec, v 16, No 4, 451-8, 7 figs on 2 pls

Nerve injury is more serious in tuberculoid than in lepromatous leprosy, but can be demonstrated in both forms. A histological analysis has been made in a series of skin sections from six cases of each form of all nerve branches and of lepra bacilli in them with the following results, which are shown in two tables, and illustrated by plates. In the tuberculoid form infiltration with destruction of the nerves is the characteristic change and in the lepromatous variety infiltration and the frequent presence of the bacilli predominated. Nerve branches are more frequently found in the lepromatous variety. The greater number of bacilli with less destruction of the nerves in lepromatous lesions indicates that in the tuberculoid cases the nerve destruction is due to an allergic reaction. The lesions described are well shown in the illustrations

L Rogers

ALVAREZ LOWELL, L, PUCHOL, J R & RODRIGUEZ PEREZ, A P **Aportación al conocimiento histopatológico sistema nervioso periférico en la lepra [Contribution on the Pathological Histology of the Peripheral Nervous System in Leprosy]** *Internat J Leprosy* 1948, Oct-Dec, v 16, No 4, 459-64, 16 figs on 5 pls

The changes described were based on complete autopsies of two patients dying from the lepromatous form of the disease, and biopsy specimens of five leprosy patients of different types and in different stages. The changes are described as they occurred in the spinal ganglia, the peripheral nerve trunks and the nerve endings. Each of these is described minutely and illustrated by photomicrographs. In the ganglia appear cells, some swollen and enlarged, others staining badly and obviously degenerating, the capsules are swollen but in no case was there any proliferation of the connective tissue. There was, however, some proliferation of endocapsular glia cells, certain of the cells showed hyperpigmented masses, but no neurofibrillar structure could be made out, merely irregularities in the reticulum. The cells were much

of the nodules ensued with eventual disappearance leaving deep scars with or without discharge from the nodules in some and small fine scars in others. From two to several injections were required to destroy nodules completely. Of 51 nodules on the ear 4 were destroyed through expulsion of their contents and 7 were reduced in size. Only 7 scars could be regarded as unaesthetic. In a total of 30 cases the nodules were completely cleared up in 20 although they had previously resisted promin intravenously for 12 to 30 months. In the other 10 only partial success was obtained. Macules and plaques are present in too large numbers for this treatment owing to the intense pain and blisters resulting from the caustic nature of the drug.

Row R. On the Experimental Transmission of Rat Leprosy in the Mouse with the Culture of *Mycobacterium Steadwelli* Isolated by Symbiosis. *Indian Physician*, 1949 June v 8 No. 6 145-P 2 pls.

After reference to his previous paper on the cultivation of the bacilli of leprosy and of rat leprosy by symbiosis [see this *Bulletin* 1949 v 48 264] the author records a single experiment of inoculation of a mouse intraperitoneally with rat leprosy material. When the mouse was killed after five months the liver and spleen were much enlarged and studded uniformly with pin-head granulomata containing globi and numerous acid-fast long bacilli which were cultivated by the author a method on glycerinated potato. This culture produced similar appearances when injected into a second mouse.

HELMINTHIASIS

GÄRTNER, H & MÜTTE, Lieselotte. Beitrag zur Verbreitung der Wurmkrankheiten. [On the Spread of Helminthiasis.] *Deut med Woch.* 1949 July 15 v 74 Nos. 27/28 831-3. 18 refs.]

Helminthic infestation seems to have been increasing in Germany in recent years. Even before the war it was fairly high. From East Prussia in 1892 came records of 74 per cent *Ascaris* and 53 per cent *Trichuris* infestation. In Kiel in 1936 a general infestation of 4-6 per cent with 78 per cent *Trichuris* and 28-3 per cent *Ascaris*. Outside Germany also incidence was high, in Italy Switzerland and Russia between 30 and 40 per cent in 1943 between 31 and 55 per cent in Italy in 1922 27 between 29 and 50 per cent in Russia. (These are given as general figures of worm infestation but they cannot surely apply to the whole of these countries.) The first-named author (Gärtner) in 1943 examined in France Frenchmen employed in German kitchens and found 16 per cent infested among Germans similarly employed only 7.1 per cent. In Russia more than 30 per cent.

In Darmstadt after the war helminthiasis was very rife. 77.5 per cent of those examined (number not stated) were infested, the main source being it appears, vegetables and fruit (strawberries) grown on irrigated soil, untreated waste-water being used for the irrigation. The authors examined 1044 persons the stools of 1040 and anal smears of 152. Of 783 faecal samples sent in to the Hygiene Institut 496 (63.3 per cent) were positive. *Ascaris* in 761 (77.8) and *Enterob* in 578 (73.8). *Trichuris* 23 (4.8) and *Taenia* 8 (1.6). Thirty were examined from the kindergarten. 1 stool used *Enterob* 3 *Ascaris* and 3 had both. Of 46 anal smears from the Children's Clinic *Enterobium* was found in 41. One hundred and twenty-three young girls between 20 and 23 years of age at High Schools with hygienic conditions above the average had their faeces examined and 73.59 per cent were positive. 43

with *Enterobius*, 23 with double infestation and 7 with *Ascaris* alone, in 65 out of 104 the anal smear was positive. Of 82 workers in the irrigated fields 65 were positive. The irrigation water was examined, two samples being taken in the morning, at midday and in the evening and the average number of *Ascaris* ova found was 530 per cc, the extremes being 464 and 568. Since the accepted length of life of *Ascaris* ova in soil is 5 years, those working in these fields irrigated with untreated water are in perpetual danger of infestation.

ALBORNOZ PLATA, A. El examen coprológico. Valorización estadística del método de concentración sobre el método directo [Faecal Examination Statistical Evaluation of Concentration as compared with Direct Examination] *Prensa Méd Argentina* 1949, May 27, v 36, No 21, 944-6

The author has compared the results of direct examination of the faeces and a concentration method which he calls the American Armada [this is not defined] in 88 children, 8-16 years of age, in Bogotá, Colombia. He determined the percentage coefficient of infestation by *Ascaris*, *Trichuris*, *Giardia* and hookworm, and shows how much more satisfactory the concentration method is. Thus, the direct coefficients were 22.6, 53.4, 17.7 and 10.2 per cent respectively, whereas those by concentration were 39.8, 69.2, 20.5 and 17.0.

He concludes that a negative direct examination is valueless, a positive has a qualitative, but not a reliable quantitative, value, and, secondly that concentration methods should be used in all laboratories. [He might add that, for purposes of inter-laboratory comparison, one particular concentration method should be agreed upon.]

RAVELLI, A. Zum röntgenologischen Erscheinungsbild höherer tierischer Parasiten in der Lunge des Menschen [X-Ray Appearances of the Higher Animal Parasites in the Human Lung] *Med Klin* 1949, May 13, v 44, No 19, 603-6 [Numerous refs.]

In the author's view X-rays of the lungs can be of considerable help in the diagnosis of certain worms and arthropods. He describes the appearances in the following 7 infestations —

1 *Schistosomiasis* — In the acute state milky shadows, of the size of millet seeds, distinguished from tuberculosis because the apices are free, later the shadows are larger, to the size of a pea or even bean.

2 *Paragonimiasis* — Extensive diffuse bronchiectasis with shadows about 8-10 times as large as a pin's head.

3 *Cysticercosis* — Small opacities up to 4 mm, rounded or oval, umbilicated. Extrapulmonary cysticerci, calcified and uncalcified, may be seen.

4 *Echinococcus cyst* — Usually solitary, varying greatly in size from that of a pea to that of a human head, mostly homogeneous. The *Ablösungsphänomenon* may be seen — a clear half-moon zone due to the presence of air between the cyst and the lung tissue at the upper pole of the cyst, or the symptom which the author calls *Kopfsteinpflaster*, in which the daughter-cysts floating in the mother-cyst produce an undulating borderline.

5 *Echinococcus alveolaris* — Coin-like shadows, from a pea to a walnut in size, with clear-cut but irregular borders.

6 *Pentastomiasis* — Usually subpleural in position, the size of a pea, kidney-shaped non-homogeneous opacities with a clear-cut edge. The larva may or may not be calcified.

7 *Porocephalasis* — Opacities millet-seed in size and trapezoid in shape, with double-contoured rings and typical segmentation. Extrapulmonary calcified forms may be seen.

CALDERÓN RODRÍGUEZ, Judith. Algunos datos sobre antihelmínticos intestinales. [On Intestinal Anthelmintics.] *Rev. Kuba Med. Trop. y Parasit.* 1949 Mar.-Apr., v 5 Nos. 3,4 41-7 [Bibliography]

A useful summary of the subject. In fact it seems to have been a lecture delivered to the Parasitological Section of the National School of Biological Science, Mexico. The author notes first the difference between vermifuges and vermicides and then divides active anthelmintics into four groups: 1. Crude drugs as used by indigenous populations. 2. Refined or partially refined products of these. 3. Active principles of them, isolated and purified. 4. Synthetic products.

Various drugs—male fern, pomegranate, pumpkin seeds, pelletierine and terpenes, antimony, chenopodium and avaricidol, phenols (thymol, resorcin, hexyresorcinol), gentian violet, carbon tetrachloride and tetrachlorethylene and others—each receive a few words on their doses and special uses. A bibliography of nearly 60 titles is appended to the paper. *II Harold Scott*

DE AZEVEDO J. F., DA SILVA, J. B., COTTO A. DE M., COELHO M. F. & COLAÇO A. O foro português de schistosomíase. [The Focus of Schistosomiasis in Portugal.] *An. Inst. Med. Trop. Lisbon.* 1949 Dec., v 5, 175-222, 20 figs. (15 on 6 pls.) (43 refs.) English summary

The discovery recently of two cases of urinary schistosomiasis (*S. haematobium*) in the Province of Algarve at the south-west corner of Portugal led to an intensive study of the endemism of this infestation. The authors have carried out a very thorough investigation and their work and its results are presented in much detail in this paper. They give a history of the disease in Portugal, the first case having been reported from the same district in 1921. Some 10 villages were studied, but in only one, Estoi, was infestation found as recently as 1948. In one other, Estômbar it was found in 1948, and in a third, Marmeleira, in 1942. Molluscs are abundant in the waters of the Province, particularly *Planorbis d. fontis*, many of which were infested; others are *Physa* *acuta* and *Lymnaea stagnalis* but these do not seem to be intermediate hosts. In some of the other villages cases have been observed during the past 20 years and there is every possibility that the infestation may spread to them again since the vectors are numerous and the people infested habitually bathe in local ponds and streams and in irrigation tanks. Experimentally, a *Cercopithecus* monkey was found infectable by cutaneous penetration of the cercariae and also per os and lesions in the intestine and liver resulted, but on no occasion were ova seen in the urine. Much of this paper is taken up with an ecological study of the molluscan vector. One case in a man of 71 years is described fairly fully.

PRATES, M. A bilharrose na África Oriental Portuguesa e a sua importância na etiologia dos carcinomas primitivos do fígado dos indígenas. [Schistosomiasis in Portuguese East Africa and its connection with Primary Carcinoma of the Liver.] *An. Inst. Med. Trop. Lisbon.* 1949, Dec., v 5, 149-74, 31 figs. on 10 pls. English summary

Carcinoma of the liver is unduly common among the indigenous population of the Mozambique. It affects even children as young as 10 years of age though more frequent among adults of 20 to 35 years. Early symptoms are a feeling of weight and slight pain in the epigastric region or right hypochondrium; a month or so later swelling appears, often nodular. This is followed by ascites and the fluid may be haemorrhagic; pruritus appears before death. Cachexia is rapid. At autopsy the liver shows one or a mixture of four forms: 1. Great

enlargement, to 8 kgm or even more, with nodules on the surface varying in size from that of a grain of millet to an orange 2 Liver small and made up of hard tumours like a bunch of grapes 3 Often seen in children, liver small and cirrhotic with small nodules, resembling Laennec's cirrhosis 4 One lobe almost entirely replaced by neoplastic tissue, perhaps as large as a "child's head", with a surface smooth in some parts, nodular in others The bile-ducts are free of growth but the portal vein is nearly always dilated and occupied by tumour masses

Seeing appearances so like cirrhosis the author naturally thought of native drinks which are taken freely and are often irritant and contain toxic substances of an aromatic or resinous nature [not specified], but this would not account for many of the cases occurring in children Further investigation revealed that nearly every individual suffered from schistosomiasis (*S haematobium* in this district) and microscopical examination of the liver tissues showed that schistosome ova were present, and the author believes that this infestation is the cause of the primary carcinoma common among these people It was thought that if this were so confirmatory evidence might be obtained by examination of the livers of animals infested with *S bovis* The author therefore obtained material from the slaughter-house and found the same histological changes, indicating malignancy, in the livers of cattle similarly infested Some excellent photographs illustrate the paper

DA MOTA, L A C-R C Estudo da acção do gamahexano sobre alguns moluscos portugueses dos géneros *Planorbis*, *Limnaea* e *Physa* [On the Action of Benzene Hexachloride on certain Molluscs of Portugal] *An Inst Med Trop* Lisbon 1948, Dec, v 5, 289-319 English summary

This article is divided into two parts In the first, the author carried out a comparative study of the effect, under laboratory conditions, of BHC and of copper sulphate on *Planorbis dufourii* (the vector of *S haematobium* in Algarve Province), *Limnaea peregra* and *Physa acuta* For the former, he used 10 cc of a solution of a commercial product, L F 140, containing 10 per cent gamma isomer, with 90 cc distilled water and 0.4 cc of Triton X 100 The copper salt was used in a dilution ranging from one in a hundred million to one in a thousand The detailed results are given in tables, but the following epitomizes the results

1 Copper sulphate in a dilution of 1 p.p.m. upwards will kill all three in 24 hours, whereas BHC requires a concentration of 100 p.p.m. to give the same result

2 BHC is more expensive than the copper salt

3 BHC may endanger the life of the higher aquatic fauna and animals using the water

4 *P. dufourii* is more resistant to BHC than are the other two, whereas

5 From a few experiments it would appear that *Planorbis* and *Physa* are both very sensitive to copper sulphate Hence

6 The copper salt is to be preferred for dealing with *P. dufourii*, the local vector of *S haematobium* in Algarve

The second part of the paper deals with the action of BHC on the development of the ova of *P. dufourii*, controls being maintained in water under similar conditions The author found that with concentrations of 0.1 to 0.2 p.p.m. the motility of the embryos was reduced and the hatching period of the eggs lengthened and all embryos died in 3-4 weeks In higher concentrations of 1 to 5 p.p.m. they died in 2 weeks and in 10-20 p.p.m. in one week 0.02 p.p.m. had no effect on the embryos during a period of observation of 35 days "On account of the very high concentration needed to kill the embryo snails we do not consider the use of gammexane practicable for this purpose"

COUTINHO J. O. & PRADO, S. B. Sobre um foco autóctone de esquistossomose mansônica em Jacareizinho (norte do estado do Paraná Brasil). (A Focus of *Schistosomiasis mansoni* in Jacareizinho, Paraná.) *Hospital* Rio de Janeiro. 1949 Apr., v 35, No. 4 531-42, 3 figs. & 1 plan. [14 refs.]

Schistosomiasis mansoni has been recorded in Paraná by Pinto and Almeida, but the exact locality was not given. The authors now report finding a focus of infestation in Jacareizinho, a town in the north of the State. They examined the stools of 51 persons and found ova of *S. mansoni* in 20 of them, all young persons below the age of 20 years—the ages ranged between 6 and 18 years and all had been born in the town and had lived in the municipality all their lives. The intradermo-reaction was tried on 68 subjects (including the 20 with ova in their faeces)—19 gave a 3-plus, five a 2-plus, and eight a 1-plus. Eight of those with faeces positive gave a negative skin reaction and the opposite of this was still more frequent—four who gave a 3-plus had negative faeces—three who had a 2-plus and seven who had a 1-plus. The chief focus of infection was the stream Agua Fria near an old reservoir (piacina). *Australorbis glaberrimus* was found in the waters. Unless care is taken there is a danger of the spreading of the infestation beyond this small focus as conditions therefor are favourable.

VITAN SENA, S. C. Chromosomen und Geschlecht bei *Bilharzia mansoni* (Chromosomes and Sex in *Schistosoma mansoni*). Reprinted from *Zeitschr. f. Parasitenk.* 1949 Aug 30 v 33 No. 5, 690-701, 17 figs. [Numerous refs.]

GÖNNERT R. U. ber rudimentär weibliche Geschlechtsanlagen bei *Bilharzia mansoni*-Männchen. (Rudimentary Female Embryos in *Schistosoma mansoni*). *Zeitschr. f. Tropenmed. u. Parasit.* Stuttgart 1949 Aug. 1 v 3, 277-8, 5 figs. [10 refs.]

GUTIÉRREZ AGUAYO C. Precisa estudiar mejor nuestros moluscos de importancia médica. (Need for Closer Study of Molluscs of Medical Importance in Cuba.) *Rev. A. de Med. Trop. y Parasit.* 1949 Mar-Apr v 5, Nos. 3/4 47-50, 3 figs.

The author laments that little (if anything) has been done to gain real knowledge of the molluscan intermediate hosts of the helminthic parasites of his country. *Physa culensis* and *Lymnaea cubensis* are known to be common vectors of *Fasciola hepatica* and *Tropicoeris lemniscatus* and *Australorbis glabratus* of *Schistosoma mansoni*. Photographs of these are very clearly reproduced, drawn to scale.

The author suggests publication of a booklet depicting and describing the chief Cuban sweet water molluscs and indicating their distinctive point for identification—a study of the geographical distribution, experiments to determine which are capable of acting as intermediate hosts, establish malacological and zoonotic indices in as many localities possible and finally to find out the best way of getting rid of potentially noxious ones. (Much useful information might be gained from the carrying out of such a scheme.)

HIDAYAT M. A. Endemic Hepato-Splenic Fibrosis. (Endemic Hepato-Splenomegaly). (Egyptian Splenomegaly). *J. Roy. Egyptian Med. Ass.* 1949 May v 32, No. 5 404-22. 21 refs.

This paper is a concise account of the aetiology, pathology and clinical features of Egyptian splenomegaly with a review of 141 patients who were

subjected to splenectomy in the Kasr el Ain Hospital during 1943. The ages of the patients varied from 10 to 70 years, but 94.3 per cent of them were under 40. There were 120 males and 21 females. The majority came for operation within the first three years of noticing splenic enlargement. All patients showed secondary hypochromic anaemia and it is recommended that operation be postponed until the percentage of haemoglobin has been raised to 70, as in 60 per cent of the post-operative deaths the figure was below this. Schistosome ova were detected in the stools of 26 per cent and in the urine of 10 per cent, if those in whom haematuria and pyuria without ova were present are regarded as probably examples of old schistosome cystitis, then 79 per cent of the whole series were of schistosomal origin. Thorough treatment of this condition before operation is advised. Ova of *Ascaris lumbricoides* were detected in 33 per cent and of *Ancylostoma* in 11 per cent, both of which infections received appropriate treatment. Leucopenia below 2,500 or leucocytosis above 11,000 per cmm should contraindicate splenectomy and an estimation of the number of platelets per cmm is essential, as there is an increased tendency to haemorrhage in patients with thrombocytopenia, or to thrombosis in the portal venous system in those with a high platelet count. In selecting patients for splenectomy preference should be given to those under 40 years of age with a comparatively short history, the risks of operation increase as the cirrhosis of the liver advances and ascites, jaundice or any sign of hepatic insufficiency are absolute contra-indications. The galactose tolerance often fails to detect mild degrees of hepatic insufficiency, other more sensitive tests are therefore recommended, especially the bromsulphthalein clearance test of Rosenthal, provided that jaundice is absent.

Splenectomy was carried out through a long left paramedian incision in the usual manner, if diffuse firm adhesions are met with or the spleen is felt to its bed the author advises that the attempt at removal be abandoned and as much of the pedicle be ligated as can be safely reached. Silk should be used for all ligatures and auto-transfusion of the citrated splenic blood during the operation is advised. The operation mortality was 10 per cent, due to post-operative shock in five cases, spinal shock (after percaïne anaesthesia) in two cases, pneumonia two cases, burst abdomen three cases, cholaemia one case and streptococcal septicaemia one case. Pulmonary collapse and pneumonia occurred in 61 cases (40 per cent), including the two deaths referred to above, various factors probably contribute to this high incidence, such as trauma to the diaphragm during operation and the loss of the support provided by the enlarged spleen (Henry), but the main factor is obstruction of a bronchus by mucus and inability of the patient to expectorate it as a result of weakness or inhibition of the respiratory muscles. Early movements, cough and expectoration should be encouraged and frequent short inhalations of a mixture containing 5 per cent of CO₂ in oxygen after operation are advised. [A follow-up of the survivors, with blood examinations where possible would have added greatly to the value of this analysis.]

W. L. Harnett

COUCEIRO, A. Esplenomegalia esquistosómica gigante. Esplenectomia [Great Enlargement of the Spleen in Schistosomiasis. Splenectomy] *Semana Méd* 1949, July 21, v 56, No 29, 115-29, 2 figs [46 refs]

This article is of the nature of a lecture on splenomegaly, with an illustrative case of a young girl of 17 years who, from the age of 12, began to suffer from pain and swelling in the left hypochondrium. When she came under the author's observation there was little or no pain, but the spleen extended down to the iliac fossa and two fingers' breadth to the right of the middle line. Eosinophiles made up 10 per cent of a total leucocyte count of 4,200 per cmm, in the

laeces were ova of *Isurus lambricoides*, *Incisostoma duxleyi*, and *Schistosoma mansoni*. (The author reproduces a photograph of a man with splenomegaly just like that of the girl in question, because at the time of examining the girl a camera was not available." Splenectomy was decided upon and a photograph of the organ is shown. Its measurements were 21x18x8 cm., weight 2,300 gm. Recovery was uneventful and the patient left hospital in a month.

The remainder of this article is taken up with general text-book matters, such as the physiology of the spleen, enumeration of the causes of splenic enlargement, quotations from and references to the literature on spleen in schistosomiasis, concomitant conditions as regards the blood, urine, liver function, serological reactions and the various reasons for which authors from the beginning of the century have suggested extirpation of the spleen.

ARMBRUST A. de F. Esquistosomose da vesícula biliar (Schistosomiasis of the Gall-bladder. Hospital, Rio de Janeiro, 1949 Apr v 35 No. 4 467-69 13 figs. [40 refs.] English summary.

The author remarks on the rarity of involvement of the gall-bladder in schistosomiasis—35 references to it have been collected by him—and he notes that it has been recorded in a patient in Brazil who had undergone the operation of cholecystectomy. He here records two cases of his own. The patients gave a history of repeated haematemesis and died soon after admission to hospital. Varices were found at the termination of the oesophagus. Microscopical examination of the wall of the gall bladder revealed inflammatory changes and the presence of ova of *S. mansoni*. The pathological changes are well shown in a series of photomicrographs.

JORDING, W. H. The Eradication of Schistosomiasis: a Plea for a Rational Approach to the Problem. *J Trop Med & Hyg* 1949 June 52, No 6, 171-6. [31 refs.]

Much of this paper consists of a review of recent work on mass treatment and methods of snail control, but the author concludes that efforts in these directions are not likely to be effective in control of the disease. The drugs used are not without danger, or are not so satisfactory that reliance can be placed on them, and the methods of snail destruction can hardly be applied on a scale large enough to cope with what is now an immense problem. The author describes a case in which the patient died a few days after completion of a course of intravenous injections of sodium antimony tartrate in which 10.5 grams were given in two days.

The author's plea for a rational approach is based on the failure of treatment and of snail eradication by chemical compounds, to control schistosomiasis and his proposal is that emphasis should be placed on sanitation and education. If proper means for disposal of excreta and refuse were widely available and the people knew the importance of using them properly, not only would infection of snails be averted, but the snails themselves which flourish in contaminated water would be reduced. (The author makes the point that mass treatment is not likely to be successful in eradicating *S. japonicum* because the animal reservoirs are so numerous. It seems likely that this fact would seriously interfere with the success of any scheme of sanitation for the same reason.) Good sanitation of course would exert a favorable effect on many more diseases than schistosomiasis.

*Denotes a new host record

The two species of cercariae were proved capable of causing typical schistosome dermatitis by laboratory experiments. In addition, one investigator who was naturally exposed to infection in Green Lake showed severe allergic symptoms on reinfection about one month later, and one who was infected in the laboratory showed a similar severe allergic reaction after natural exposure 27 days later. Sensitivity can therefore be greatly increased after first exposure, but it is not known how specific this sensitivity is to the different schistosomes.

Charles Wilcocks

SILVER, C P **Hydatid Cyst and Cirrhosis** [Memoranda] *Brit Med J* 1949,
 Aug 20, 423, 1 fig

This case refers to a woman of 68 who was admitted to hospital in Edgware, vomiting blood and in a semi-conscious condition. She had lived all her life in Lancashire and was not an alcoholic. She had had two abdominal operations in early life and a third in 1931. The only notes available stated "laparotomy—hydatid cyst". She had a haematemesis in 1944 and recovered. Despite treatment, she died 36 hours after admission. Autopsy showed evidence of multilobular cirrhosis and the right lobe was replaced by a cavity, 18 cm in diameter, which contained turbid fluid. The walls consisted of a layer of fibrous tissue, compressed liver tissue and a shaggy inner surface [illustrated in a photograph]. There was no calcification. Microscopically, the vascular collagenous cyst wall showed no liver parenchyma.

The thick-walled cyst had existed for many years, but had distended instead of becoming shrunken and calcified.

The rarity of this combination in the literature is briefly discussed, but the author suggests that it seems unlikely that the cyst and the curculion were present together by chance. This cyst was almost certainly hydatid in origin and had probably existed since childhood. The great age of the cyst and its persistence after the death of the parasite may have had a bearing on the development of curculiosis.

DE LIZENZO, J. F., ROQUE, R. DE A., COLAÇO, A., CRISTINO, E., RÊS, J. F. & COLLASO, M. F. A aniclostomíase rural em Portugal. I. Rural Ankylostomiasis in Portugal. *An. Inst. Med. Trop. Liabon.* 1948 Dec. v. 5 31-69. 12 figs. 14 refs.]

The English summary appended to the paper is as follows —

1. Ankylostomiasis is still existing in Portugal as a rural ankylostomiasis entity infesting a large area in the suburbs of Coimbra (center of Portugal).

2. This parasitosis is spread in some localities of the region, among which Vilarinho 66-5 of the population is infested causing sometimes severe anemias.

3. The Ankylostomidae although more frequent among children from 5 to 10 years old were found in one child aged 18 months and in an old man aged 60 years. The boys are more affected than the girls and they show lower rates of hemoglobin.

4. The infestations are mild in the majority of cases and as maximum one case with 278 worms was found.

5. Besides Ankylostomidae the *Acaris lumbricoides* and *T. trichocephalus* also infest also largely the local populations.

6. The characteristics of the region, such as temperate rainfall nature and hydric richness of the soil, irrigation system of the land and its methods of cultivation are favourable nearly all around the year to the evolution of the eggs of Ankylostomidae and to the longevity of the infesting larva.

7. The precarious hygienic habits of the population and its agricultural occupation contribute largely to the maintenance of the endemic focus.

8. The gravity of the manifestations of Ankylostomiasis per se, the character of malignity it transmits to the intercurrent diseases, the economic deficit it certainly conveys to the parasitized populations and the possibility of the spread of this disease from this focus to other regions of the country urges its extermination. We advise as a prophylactic base the treatment of all patients during the winter season.

VOGEL, H. & MÜLLER, W. Beiträge zur Klinik der Lungen-Ascariasis und zur Frage der flüchtigen eosinophilen Lungeninfiltrate. *Communication on Pulmonary Ascariasis and Transient Pulmonary Eosinophilia*. Reprinted from *Beiträge z. Klin. u. T. Tuberkulose* 1942, 101, No. 8 670-53. 15 figs. 74 refs.

The authors prevailed upon six volunteers between the ages of 30 and 49 years, there is no indication of their being prisoners of war. How certain number of ova of *Ascaris lumbricoides* with some other remains, what clinical

symptoms and X-ray appearances (if any departure from the normal) and blood and sputum changes occurred, whether the clinical picture corresponded with an eosinophilia, and how many ova were needed to produce these symptoms. The numbers of ova swallowed varied from 6 to 45. Nine to twelve days after the ingestion, the X-rays revealed slight pulmonary shadows reminiscent of a mild bronchitis and lasting for three to six days. This was accompanied by a feeling of faintness, pain in the joints, headache, a little breathlessness and a dry cough. Those who had taken the larger amounts, 21 and 45 ova, had higher fever and some crepitations in the lungs. Expectoration was slight, greyish-yellow in colour and microscopically showed some red corpuscles, Charcot-leyden crystals and eosinophiles, but no *Ascaris* larvae. The degree of eosinophilia varied, in two of the subjects it was very low, but in one who had taken 45 ova eosinophiles comprised 38 per cent of a total leucocytosis of 10,600 per cmm on the 18th day, 52 per cent of 10,800 on the 20th, and 36 per cent of 8,600 on the 23rd day. Together with the lung symptoms, signs of allergy were noticed: urticaria, pruritus and facial oedema. It is argued that *Ascaris* larvae may be a cause of Loeffler's syndrome. [This contribution was received by the Journal in question in July, 1942, but even then it was known that the larvae of *Ascaris* in their development passed through the lungs and that, apart from a general eosinophilia, the presence of worms or their ova was associated with local eosinophilia. See also this *Bulletin*, 1949 v 46, 871.]

GUHA, P K An Interesting Case of Round Worm Infection with Post Mortem Report *Calcutta Med J* 1949, Apr, v 46, No 4, 115

A young Madrassite of about 25 was admitted to a hospital in Bangalore in 1944 with abdominal pain and vomiting of three days' duration. Three times in hospital, he vomited 30 to 40 roundworms. Despite general and supportive treatment, he died a few hours later. At autopsy "handfuls" of roundworms were emerging from the nose and mouth. There was no sign of peritonitis, but there was a rent of 3½ inches in the greater curvature of the stomach, nearly 200 roundworms were projecting from this opening. Two pockets of roundworms were found in the liver, and one each in the pancreas and the spleen.

It is suggested that the marked under-nutrition and low resistance of this patient played a part in the dissemination of the parasite in these three organs.

H J O'D Burke-Gaffney

GURTNER, H Toxische und antigene Eigenschaften von Ascaridenextrakten [Toxic and Antigenic Properties of *Ascaris* Extracts.] *Ztschr f Hyg u Infektionskr* 1948, Aug 17, v 128, Nos 3/4, 423-39 [28 refs]

The varied character of the symptoms due to *Ascaris*—diarrhoea, vomiting, cramps, and urticaria, conjunctivitis and asthma indicating allergy—is in favour of there being not one single toxin but a combination of them. The author obtained specimens of *Ascaris suus* and prepared four extracts therefrom. Complete extract, protein, carbohydrate and lipid. Minute details of the preparation are given in the paper, those interested should turn to the original, the account is too full for reproduction here. They were then tested by subcutaneous injection into guinea-pigs and rabbits. The first three were dissolved in physiological saline, the fourth in sterile neutral olive oil. The former three were injected in quantities of 1, 2 and 2 cc at intervals of three and two days respectively, the lipid extract intragluteally in doses of 0.5, 1.0 and 1.0 cc at the same intervals. The strongest reactions produced were red or pale

papules 6-8 mm. in diameter visible in 24 hours and remaining for nine days or longer. Complement fixation reactions were also carried out with the sera of immunized rabbits.

Cutaneous tests were also made on 1 human subjects seven with a clear history of *filari* infection, three doubtful and two negative. The results of all these tests animal and human are given in a series of protocols, but may be epitomized as follows. The protein and complete extracts were more potent for guinea-pigs than the other two and the protein more than the complete. Injected intravenously both are rapidly fatal. Both contain a histamine-like substance but it is not histamine itself. Intracutaneously injected into rabbits the complete extract and the lipid fraction were more toxic than the carbohydrate fraction and the latter more than the protein fraction. Complement fixation tests showed that all four extracts possessed antigenic properties. In cutaneous tests on the human subject the protein fraction proved to be the most active and after it in order the complete extract the lipid fraction and, least the carbohydrate fraction.

HOZAN, Z. Age-Acquired Resistance and the Influence of Diet and Light on the Parasite *Ascaris columbae* in Pigeons. *Bull. Inst. Marine & Trop. Med. Acad. Gdansk Poland* 1948, 1, 1, 29-44.

HAFEZ, A. H. Localized Filarial Mass of the Breast simulating Carcinoma. *J. Roy. Egyptian Med. Ass.* 1948 May v 32, No. 6 429-31 figs.

A widow aged 50 had noticed a painless mass in the upper outer quadrant on the left breast for 15 days. The skin of the affected breast was tougher and thicker than that of the other breast, the mass was firm, irregular in outline and fixed in the breast substance adherent to the skin, but not to the underlying muscles. The axillary nodes on the same side were enlarged, not tender and not adherent to each other or to the surrounding structures. There were no other physical signs. Scirrhus carcinoma of the breast was diagnosed and operation advised, which was refused but a biopsy under local anaesthesia was allowed. The mass had the naked eye appearance of carcinoma, but microscopy showed a granuloma containing foreign bodies, which on serial section proved to be portions of a filaria. Subsequent enquiry elicited that the patient lived in a district heavily infested with filaria unspecified but had never suffered from lymphangitis or other filarial manifestation. A microfilariae were found in the blood. In Egypt filariae of the breast usually gives rise to diffuse lephangitis and no report has hitherto been made of localized mass simulating carcinoma.

B. L. Harrell

GALLIARD H. & MILLE H. Essais de traitement de la filariose à *Wuchereria bancrofti* var *Pacificus* par le 1-diéthyl carbamyl, 4-méthyl piperazine à Tahiti. Studies in the Treatment of Filariasis due to *W. bancrofti* var *Pacificus* by 1-diethylcarbamyl 4-methyl piperazine in Tahiti. *Bull. Soc. Path. E. M.* 1949 v 42, No. 5 6 304-13.

Six patients in Tahiti were given 20 mgm. per kgm. of Hetrazan by mouth three times a day for 7 days. The number of microfilariae in the blood fell very rapidly so that within six hours 70-80 per cent. had already disappeared. For 98 other patients the dose was only 25 mgm. three daily for 4 days and 50 mgm. three daily for 3 days (owing to shortage of supplies). 87 per cent. were free from microfilariae at the end of treatment and the others showed great reduction in the microfilarial count. Sixty five patients were followed for 4 months. 47 per cent. showed slight relapses (1-10 microfilaria per 20 mm.).

14 per cent showed heavy relapses and 15 per cent remained free from microfilariae. An attempt was made to treat some patients with single daily doses (2.4 mgm per kgm) but the reactions were too severe and the sterilization was less complete. The treatment is well tolerated and even if reactions do occur in carriers of microfilariae they do not necessitate interruption of treatment.

As regards *general reactions*—The most common symptom is fever, which is usually moderate (37.8–38.5°C) and which comes on at end of the first day, lasting only a day or two. Aches in the head, loins and joints, rigors and tinnitus may also occur. Two cases of benign epistaxis were seen. As regards *reactions of special systems*—Nausea was common. Vomiting occurred only in three subjects, who each expelled many *Ascaris*. Pruritus was common, in three patients there was an intense bullous eruption localized in one of the superior members. These skin reactions are probably allergic reactions due to the destruction of worms. The circulatory and urinary systems were not affected. In some cases there was painful enlargement of the epitrochlear gland or a lymphangitic crisis, which might be interpreted as due to the death of adult worms. [These reactions differ in many ways from those of patients with *W. bancrofti* treated in East Africa, the difference may be due to the different variety of filaria involved.] A pronounced eosinophilia occurred after an initial fall. Examinations of the blood suggested that there might be an increase in the proteins of the plasma.

Experience with patients showing clinical symptoms of filariasis is limited. In five early cases of filariasis with lymphangitis, pain subsided quickly but the signs of inflammation receded more slowly. Other cases of lymphangitis in older patients were also treated but the results were too variable to allow of definite conclusions being drawn. One case of lymph scrotum cleared up well under treatment. In haemato-chyluria no permanent effect was produced. It is noted that cases of acute lymphangitis due to filariasis responded very quickly to benadryl or neo-antergan 50 mgm 3–4 times daily for 2–4 days, this supports the view that such lymphangitis is allergic in origin.

It seems potentially possible by combining the destruction of microfilariae with the destruction of mosquitoes to prevent the constant reinfestation which occurs in Oceania.

F. Hawking

HAWKING, F & LAURIE, W. Action of Hetrazan on Filariasis and Onchocerciasis. *Lancet* 1949, July 23, 146–7.

Hetrazan, 1 mgm per kgm body weight twice daily or 0.5 mgm per kgm thrice daily, removed most microfilariae of *Wuchereria bancrofti* from the blood of man, smaller doses did not clear the blood. Larger doses, 12–20 mgm per kgm daily, cleared the blood usually in three days or less, but rarely a few embryos persisted during the whole of the observation period, which was three months. A single dose of 20 mgm per kgm sufficed in most patients to remove most of the embryos. After giving the drug by mouth in the evening when the microfilarial tide was rising, 60–80 per cent of the embryos disappeared from the blood within half an hour, and after the drug was injected intravenously, 60 per cent of the embryos disappeared in four minutes. On the other hand, embryos lived for several days *in vitro* in contact either with solutions of the drug or with serum from a patient who had received the drug an hour previously, furthermore, embryos persisted in the fluid of hydroceles in patients whose blood had been rendered free from microfilariae by treatment with the drug and in hydroceles into which the drug had been injected. It seems, therefore, that the drug is neither directly toxic to the microfilariae nor does the body change it into a filaricidal substance. It is suggested that the observations support the hypothesis that the drug acts by sensitizing the microfilariae for phagocytosis.

by the reticulo-endothelial system to which they are exposed in the blood stream. It is implied that the embryos do not come into contact with large phagocytes in serous cavities and therefore are not destroyed.

Owing to allergic reactions small doses of drug were used against onchocerciasis, a common dosage being 50-100 mgm. per patient [presumably about 0.75-1.5 mgm. per kgm.] twice daily for the first two days and thereafter 150-600 mgm. twice daily with this dosage embryos sometimes disappeared from the skin after 2-3 days but in other cases persisted for more than 10 days despite continued treatment. Active adult worms were found in nodules excised from 5 of 7 patients who had had 5-12 mgm. per kgm. per day for 13-23 days and active embryos were found in the nodules of all the seven patients. The maximum tolerated single dose of Hetrazan for man appeared to be about 20 mgm. per kgm. body weight. In patients with *H. bancrofti* this sometimes caused nausea and vomiting, with or without epigastric pain, and occasionally produced tender spots in the groin or scrotum. In patients with *Onchocerca* even a single dose of 50 mgm. [presumably less than 1 mgm. per kgm.] always produced a violent reaction which was well marked in 18 hours. There was usually swelling, oedema, itching and tenderness of the skin, with sometimes a papular rash and enlargement and tenderness of the lymph glands and always pyrexia up to 101-102°F. The symptoms subsided after a few days and the patients could then tolerate much higher doses, e.g. 1 mgm. per kgm. daily. The severity of the reaction seemed proportionate to the number of embryos initially in the skin. The authors feel that this allergic reaction is sufficient to make Hetrazan unpopular were it to be used for the mass treatment of onchocerciasis. (These allergic reactions seem to be a feature of the treatment of filariasis with Hetrazan and to be especially marked in onchocerciasis. It seems worth while endeavouring to diminish their severity by the use of sedatives and anti-histamine drugs.)

F. Margatroyd

BARCOO E. Essai de traitement de la filariose (*F. loa* et *F. perstans*) par le 3-789 R.P. Therapeutic Trial of 3,789 R.P. on Filariasis due to *Loa loa* and *Loa loa* (*Loa loa* and *Loa loa*). Bull. Soc. Path. E. 1949 v. 4, No. 4/6, 313-17.

The studies were carried out in the region of Ayos in French Cameroun. 3,789 R.P. is Hetrazan, i.e. 1-diethyl carbamyl-4-methyl piperazine. Five patients infected with *Loa loa* and 4 *perstans* were treated with doses up to 5 mgm. per kgm. twice daily. Microfilariae of *L. loa* were removed from the blood; those of *F. perstans* diminished or disappeared but the author does not attach great significance to this. During the discussion on this paper St. I. Nopoulos described a case of onchocerciasis in a European, whom the allergic reactions to Hetrazan had been so violent (in spite of anti-histamine drugs) that the patient had refused to continue the treatment.

KOHLER C. L., BRUNA H. W., WILLIAM R. W. Filariasis Control by DDT Residual House Spraying, Saint Croix, Virgin Islands. I. Operational Aspects. KOHLER, C. L. P. S. H. 4th F. P. W. 4th 1949 July 8, 64. No. 77 857-62. II. Results. BRUNA & WILLIAM. J. J. 1949 5 11.

DDT applied to houses: a residual spray has been used with success for the control of adult anophelines in different parts of the world and very recently in South America for the elimination of *A. aegypti*. One species of mosquito (*A. albopictus*) appears to have been less susceptible to DDT but the mosquito in the Caribbean region is the vector of human filarial disease. The United States Public Health Service introduced the residual insecticide method to

the local authority of the island of St Croix (84 sq miles) one of the American Virgin Islands group situated to the east of Porto Rico in the West Indies. For all practical purposes the mosquito population appears to be limited to *Culex quinquefasciatus* and *Aedes aegypti*, both domestic types breeding in artificial containers of water or in polluted waters closely associated with human dwellings.

A team of local workers was trained to apply insecticide in the usual way by power sprayer, hand sprayer or both at the rate of 200 mgm DDT per square foot to walls, ceilings, porches and privies of housing of the typical sub-standard type, characteristic of a tropical country and in keeping with the low economic level of the inhabitants. At first DDT in kerosene was used, but this was soon replaced by DDT-Xylene-Triton emulsion [35 per cent DDT-Xylene concentrate, with Triton X-100, diluted with water to form a 5 per cent spray]. Spraying began in October 1946 and finished in May 1948, each dwelling on the island having been treated on four occasions. Continuation of the process was then handed over to the local health department as a "going concern" with the proviso that wettable powders might well be substituted for the emulsions because of the absorbent nature of the wall surfaces. A table provides the detail of work, man-hours and cost, all of which improved as the workers gained experience. In all, 11,078 houses (1,900 sq ft per house) were sprayed, each on four occasions, in 400 working days or 21,630 man-hours at a cost at the last spraying of approximately 1½ dollars per house.

The School of Public Health of Columbia University took the opportunity of ascertaining the effectiveness of this campaign in reducing the transmission of *Wuchereria bancrofti*. Mosquito and blood surveys were conducted before and after the 20-month period of spraying.

The mosquito survey revealed only *C. quinquefasciatus* and *Aedes aegypti* in human dwellings, samples of these were collected from the whole island and conveyed to a central laboratory for dissection. The filaria infection rates are tabulated. In 1946, 2,244 *C. quinquefasciatus* had an infection rate of 7.9 per cent, and 0.40 per cent contained infective forms of the parasite. In 1948, only 846 *C. quinquefasciatus* were collected, of which 3.65 per cent were found to contain developing forms of the filaria but no infective forms were observed. Of 867 *Aedes aegypti* caught in 1946, 2.3 per cent contained developing forms but no infective ones, while in 1948 no *Aedes aegypti* were seen in houses. The end result revealed a 57 per cent reduction in the number of houses harbouring *C. quinquefasciatus* with a 50 per cent reduction in the percentage of infected mosquitoes. In all probability survivors did not live long enough to become infective, *Aedes aegypti* seemed to have disappeared.

Blood surveys for microfilariae were conducted before the DDT programme and 21 months later. Thick blood films were made from pre-school and school children, of 1,311 examined in 1946, those aged 6 years were the youngest to show infection (6.2 per cent), the rate gradually increased with age the maximum being 25.5 per cent in those aged 13 years. The counts varied from one to 741 microfilariae per 0.04 ml of blood in the 13.3 per cent found infected. The 1948 survey of 906 children gave an infection rate of 10.6 per cent, the difference being "not quite statistically significant". However, the percentages positive in those aged 6, 7 and 8 years were considerably reduced, 6.2 to 2.9, 8.9 to 3.5 and 11.9 to 6.7 respectively. Despite variation of microfilaria counts in the same person from day to day, the authors believe that counts in groups of individuals do give an approximation of the degree of infection, the average microfilaria count for all examined fell from 74.1 in 1946 to 45.8 in 1948, the difference again "not quite statistically significant". Of 504 children examined on both occasions, 454 were negative; of the positives, 20 showed increases and 30 decreases in microfilaria counts.

As the authors point out "the microfilaria count of a long lived infection such as *M. bancrofti* will be affected very slowly by the prevention of additional infection and it seems unfortunate that the promising results obtained can be checked no further as another research group are attempting control of filariasis by treatment of all persons on the island. R. Ford Tebb

BARNETT L. C. Prévalence de *M. sonelli* chez la femme de la Guadeloupe [*Mansonella ozzardi* in a Woman in Guadeloupe.] *C. R. Soc. Biol.* 1949 Apr., v. 143 Nos. 2-4: 488-9

MARTZ J. Filariose et tuberculose pulmonaire (Filariasis [*M. sonelli ozzardi*] and Pulmonary Tuberculosis.) *Bull. Soc. Path. Exot.* 1949 v. 42, Nos. 1/2: 25-8.

The author describes a patient a native of Guadeloupe who had returned there after having spent four years in Paris as a medical student. On his return to Guadeloupe he had a severe haemoptysis and it was on this account that he sought advice. In a specimen of his sputum examined by direct smears there was a perfect microfilaria of *M. sonelli ozzardi* presumably present in the blood in this specimen and tubercle bacilli were also found. The filarial infection, which had not previously been diagnosed, was probably acquired before he first went to France because the period since his return (3 weeks) was hardly enough for development. If that was so residence for 4 years in a temperate climate evidently had little effect on the filarial infection.

In the discussion of this paper DECARIEZ referred to the general subject of parasitic diseases which produce eosinophilia in relation to tuberculosis noting that in certain investigations the incidence of tuberculosis was lower in groups of parasitized people than in those not parasitized. The eosinophilia may be a sign of a state of allergy which may itself tend to inhibit tuberculous infection. Charles H. Cockcroft

FERREIRA, F. C. & LOPES, E. M. R. Aspectos clinicos e epidemiologicos dum foco endêmico de dracunculose na Guiné Portuguesa. Clinical and Epidemiological Aspects of a Focus of Dracunculiasis in Portuguese Guinea. 1 *Inst. Med. Trop. Lisbon*, 1949 Dec. 5: 71-88. 23 figs. on 13 pls. 1 map. English summary

A very clear account of dracunculiasis as it affects five villages in the N'zara district at the north-west of Portuguese Guinea. The inhabitants of these villages total 1011. Of these 78 were examined and 186 (23.5 per cent.) were harbouring the worms and 28 of these had more than one. To compare the percentage infection in the different villages might convey wrong impression because the population and the numbers in each village who were examined varied so widely. Thus in Camabol with 583 inhabitants 406 were examined and 100 found infested 8 of them with multiple infestation thus gives a percentage of 20.6. At Caruati the other extreme there were 59 inhabitants

25 were examined, 9 were positive, 7 with one and 2 with more than one worm. This is given as 36.0 per cent infestation. Looked at thus, Tanhate with 88 inhabitants showed the highest rate, for of 68 examined 33 were positive (48.8 per cent), 8 of them with multiple infestation. Of the total 792, 197 were children [age not stated] and 36 (18.3 per cent) of them were positive, 595 were adults and 150 (25.2) were positive. Many more adult males were infested than females, 98 out of 288 males (34.0 per cent), 52 out of 307 females (16.9).

During the incubation period, *i.e.*, the time between ingestion of the embryo and appearance of the worm, 10–14 months, there may be no symptoms, but a few hours before the worm makes its appearance there may be local erythema and oedema, with pruritus and even generalized urticaria, dyspnoea and asthmatic attacks, nausea, vomiting, vertigo or syncopal attacks and nervous symptoms such as delirium or mental confusion, but these are not common. The site where the worm appears was noted in 201 instances. In the upper limb 8 (shoulder 1, upper arm 3, forearm 1, hand 3) or 3.9 per cent, in the lower limb 182 (90.5) groin 1, thigh 15, knee 13, leg 90, foot 63, and in the trunk 11 (5.5) (in the lumbar region and flank 2 each, the abdominal wall 7). These are well illustrated in a series of photographs. Synovitis and arthritis are fairly common complications and cysts of embryos may appear (these are also depicted). The crustacean host is *Mesocyclops leuckarti* subspecies *aequatorialis*, but *Daphnia* is also very common. The usual prophylactic measures are mentioned. Prohibition of those infested bathing in waters which may be used for drinking, and purification of drinking water contaminated by possibly infected crustacea.

DAENGSVANG, S. Human Gnathostomiasis in Siam with reference to the Method of Prevention. *J Parasitology* 1949, Apr, v 35, No 2, 116–21, 4 figs [15 refs.]

Gnathostomiasis has been reported in many countries in the Far East, but the largest number of cases have been from Siam. The author adds 17 more Siamese cases, the subjects, who were patients in the Siriraj Hospital Bangkok, were all women except two and were aged 18 to 80 years. The parasite, *Gnathostoma spinigerum*, was identified in each case.

The author has divided his cases into 5 clinical groups according to the tissue or organs into which the worms finally migrated. In nearly every case there was a primary phase of migration in the skin or subcutaneous tissues. The lesions were usually itchy, tender and painful, the pain was of a pricking or boring nature. There was no local oedema or pitting. Fever was usually absent. Eosinophilia was almost constant, it varied from 5 to 73 per cent.

Attacks usually lasted up to 10 days but were sometimes prolonged for a month or more, and they recurred up to six times a year. The duration of the infection varied, in one case it was three years. The infection terminated spontaneously by the rupture of mature or immature worm through the skin or mucous membrane. In other cases the worms were removed surgically.

Group 1 consisted of 6 patients in whom the swellings were mainly on the chest and abdomen, the worm did not migrate beyond the skin or subcutaneous tissues.

Group 2 consisted of 3 patients on whom the migration reached the neck and face, and involved the eyelids and eventually the eye itself. In each case a worm was removed from the eye, in two from the iris and in one from the anterior chamber.

Group 3 consisted of 3 patients who had lung symptoms after a period of cutaneous migrations. In each case a worm was eventually coughed up,

after which the symptoms subsided. In one case there was a period of meningeal irritation with semi-consciousness lasting 7 days.

Group 4 consisted of 4 patients who after suffering periods of cutaneous migration of the worms developed movable abdominal tumours. The tumours grew slowly and were tender but there were no other symptoms. At laparotomy a smooth rounded hard tumour of the omentum adherent to the ileo-caecal part of the intestine was removed in each case. The tumours were all about 6 cm. in diameter and in each a gnathostome was found in the centre of a necrotic space.

The last group consisted of one patient in whom the worm eventually presented in the soft palate.

The author refers to additional cases in which there were symptoms of haematuria and leucorrhoea when the worms migrated into the bladder and uterus respectively.

Antimonials have proved of uncertain use in this infection. Surgical removal of the worm is the only treatment.

The life cycle of this worm is reviewed (see this Bulletin 1933 v 30 711). The worms are normally found in the stomach wall of cats and dogs. The eggs pass into the bowel lumen and are excreted. A free-living larva emerges. The first-stage larva is ingested by a cyclops in which the second stage larva develops. When the cyclops is ingested by a fish the worm develops further and is surrounded by a cyst wall. Transmission to the natural definitive hosts and to man occur through the eating of the infected fish. The infective larva takes 8 months to develop into an adult the whole cycle takes 8 months.

A common medium of infection is a fermented food made mainly of fresh water fish available in the local market in Siam. Women are particularly fond of this food. The larvae are killed by boiling for 5 minutes or by leaving in vinegar (4 per cent. acetic acid) for 5½ hours. They however survive 4°C. for a month.

CHEN H T. A Human Ocular Infection by *Gnathostoma* in China. *J Parasitology* 1949 Aug v 35 No 4 431-3 23 refs.

Worms of the genus *Gnathostoma* sometimes cause skin or subcutaneous infections in man this Bulletin 1949 v 46 857. The author summarizes 29 proved cases up to 1947 together with the literature concerning this infection in man and animals in the Far East.

With three exceptions, all species identified have been *G. sp. japonicum*. One recorded from Japan was *G. hispidum* (this Bulletin 1974 v 51 960) and two from India did not appear to belong to either species. *Id.* 1930 v 7 481 1945 v 41 919.

The present case refers to a native of Canton aged 45 who had a gnathostome worm lying on the iris in the anterior chamber of the left eye the worm was successfully attracted. This is the third recorded ocular gnathostomiasis the others having been reported by MIKAZI and HASEKI *ibid.* v 31 610 both in Bengal in 1945 *ibid.* 919 1949 v 43 57.

The worm in this case was in an immature form 5.4 mm. long and 0.40 mm. wide. A detailed description of its morphology and measurement is given. Because of the nature of the Japanese booklet and the text of the book it has been tentatively identified as *G. hispidum*. The disputed question of the manner of human infection is discussed and the author thinks it likely that the patient may have been infected by eating raw fish delicacies which are popular among certain classes in Canton.

It is suggested that human gnathostomiasis may sometimes be wrongly diagnosed or easily overlooked, because of its rarity.

H. J. O'D. Burke (Ipswich)

Vol 46, No 11]

WALKINGSHAW, R A Subcutaneous Migrating Embryo as that recorded by
1949, June, v 3, No 4, 264

This would appear to be the same case of gnathostomiasis as that recorded by
SANDOSHAM [this *Bulletin*, 1949, v 46, 857] but the finger affected, the colour,
dimensions and name given to the worm differ in the two papers

MARTELLI, T & ZAFFINO, C Sulla frequenza dell'infestazione da *Oxyuris*
vermicularis nell'età infantile [Incidence of *Enterobius vermicularis*
Infestation in Infants] *Ann d San Pubblica* Rome 1949, Mar-Apr,
v 10, No 2, 370-75, 4 figs English summary (3 lines)

The authors, after quoting figures from the literature of several countries on
the prevalence of *Enterobius* infestation among children, record their own
findings among 220 children examined by them in a district of Rome They
used the "Cellophane swab method" The children both boys and girls, were of
all social grades and their ages ranged between 2 and 12 years Seventy-four
were positive Though commonest among those of school age, infestation
was also found in the very young, 2-5-year-olds They note that the ova
have been found not only in the infants themselves, but on their clothes,
sheets bedding and even on the window-sills of the rooms, so that infestation
may be dust-borne [as is well known], also that there are probably adults
harbouring the worm and acting as chronic carriers Besides the pruritus,
insomnia and fretfulness, the infestation may cause various other disturbances—
pallor, loss of weight, poor appetite, masturbation, leucorrhoea—and, in adults,
nyctophomania

BROOKE M M, DONALDSON, A W & MITCHELL, R B A Method of supplying
Cellulose Tape to Physicians for Diagnosis of Enterobiasis *Pub Health Rep*
Wash 1949, July 15, v 64, No 28, 897-901, 2 figs

The authors describe a modification of the Graham cellulose-tape technique
[this *Bulletin*, 1941, v 38, 525] which can readily be made available to
physicians and can be used by members of a patient's family
To one end of a strip of clear, transparent cellulose tape ($\frac{3}{4} \times 4$ in) is stuck
a piece of paper $\frac{3}{4} \times \frac{1}{2}$ in The tape is pressed to a clean slide (1×3 in) and
looped over the end so that a small portion adheres to the under surface of the
slide The paper serves as a tab for lifting the tape The preparation may be
mailed in a slide container

For use, the longer strip of cellulose tape is lifted from the slide by means
of the paper tab the section thus freed is looped over to expose the gummed
side, which is then made to touch the perianal region several times The tape
is then replaced on the surface of the slide, where it can be examined directly
with a 16-mm objective for the presence of *Enterobius* eggs

Experiments on the keeping power of cellulose-tape preparations are described
Those placed in slide containers and stored at room temperature while those kept
in a refrigerator or exposed to direct sunlight deteriorated Large numbers of
these slide preparations may therefore be prepared in inexpensive kits suitable
for distribution to physicians by public health laboratories and parents can
be instructed in taking the specimen in the home at a time most favourable for
recovering the eggs, e.g., at bedtime or in the morning before there has been a
bowel movement or a bath Detailed descriptions are given in the paper and
are well illustrated with clear line drawings

WIGAND R. Therapeutische Diarrhoeen zur Beseitigung der Enterobiasis vermicularis. [Therapeutic Diarrhoea for *Enterobius vermicularis* Infestation.] *Med Klin* 1949 Jan. 14 v. 44 No. 2, 51 —

According to Schöffner the length of life of *Enterobius vermicularis* ranges from 37 to 83 days. As soon as the ovary becomes packed with eggs the worm looses her hold on the intestinal wall and lies passive in the faecal stream. The author awests the passage to the exterior by giving saline purgatives, Glauber's harshad or Epsom salts, which are taken in warm water when the patient is fasting. The result must be definitely watery stools and not merely loose diarrhoeic stools, so that the fluid may act like a cataract. This treatment may be given twice in a week, but the purging should not last more than the one day and in 5 weeks the patient is usually free from worms.

DEFICIENCY DISEASES

VALLOTTOY M. Zur pathologischen Anatomie der B₂ Avitaminose (Myokard und Duraveränderungen im Rattenexperiment) (Pathological Anatomy of Avitaminosis B₂) [Internat. Ztschr. f. Lishenig. Berne 1949 v. 21 No. 1 61-83 5 figs. (47 refs.)]

The English summary appended to the paper is as follows —

~ Similar changes are produced in the dura mater of the rats after deficiency of long duration of vitamin B₂ as described in men before and in the beginning stages of the chronic haemorrhagic internal pachymeningitis. They are dilatation, hyperaemia and increase of the capillaries with formation of sprouts and close loops in surrounding places, light deposits of haemoderin loosening of the connective tissue. Trauma causes only bleeding which is of importance to the progression of the illness. Further widening and hyperaemia show the capillaries of the myocardium. The sarcolysis as described by Wernick such as classic phenomenon of deficiency of aneurin is found in the muscles of the heart walls. When the illness is of long duration, the focal muscular lesions are apt to get confluent and to be transformed in connective tissue. The decomposition of the fibrils can be only attributed to the lack of vitamin B₂ because the food of animals contains all the other necessary component especially proteins in sufficient quantity.

BEAN W. B., VILTER R. W. & BLANKENHORN M. A. Incidence of Pellagra. Studies in the Cincinnati General Hospital 1935-1947. *J. Amer. Med. Ass.* 1949 July 9 140 No. 10 307-3 1 chart

~ 1. There has been a striking decrease in the number of cases of pellagra seen in the Cincinnati General Hospital in recent years.

~ Since 1940 pellagra has occurred with increasing rarity and in the last 30 months only 1 case has been seen.

3. This change occurred during a period when active studies of the disease were in progress and interest was sustained.

"4 The cause for this decrease in unknown The most likely reason is the general improvement in the economic state of the population from which the hospital draws its patients

"5 The program of enrichment of flour and various educational activities may have served to sustain the trend but did not initiate it "

COSTA, D Pelagra associada a múltiplas desvitaminoses [Pellagra with Multiple Vitamin Deficiencies.] *Hospital* Rio de Janeiro 1945, Feb, v 27, No 2 323-39, 5 figs English summary [18 refs]

The case is described of a boy of 7 years with signs of pellagra, butterfly patch, desquamation, fissures at the angle of the mouth, with decay of teeth, discoloured gums, dry conjunctiva and loss of lustre, mentally dull, resentful, irritable, his weight was only 22 kgm and the general state of nutrition bad. The family was very poor, the child never had meat or milk, only once a week did he have fruit or vegetables, for breakfast and dinner coffee and bread, twice a week he had cornmeal

Regulation of the diet and administration of nicotinic acid and, later, liver extract brought about cure The author wishes to stress the fact that pellagra can exist without all the typical signs being present, and also that some symptoms not distinctly pellagrous according to the textbooks, may be basically so and thus clear up on anti-pellagra treatment *H Harold Scott*

SPRUE

FOX, H J Observations on the Proteolytic Activity *in vitro* at Neutral Reaction of Gastric Juice from Patients with Sprue *J Clin Investigation* 1949, July, v 28, No 4, 687-9

"1 When equal quantities of normal human gastric juice and 1 per cent casein solution are incubated at 37.5°C and pH 7.4, there is a progressive increase in filtrable nitrogenous substances The proteolysis was not considered to result from pepsin because the activity was maximal at pH 7.4 Also, since there was no significant increase in amino nitrogen within 24 hours, together with the persistent increase in total filtrable nitrogen after exposure to pH 10, it is considered that the proteolysis was not due to trypsin

"2 The proteolytic activity of the gastric enzyme at neutral reaction, is present to a normal degree in cases of sprue in remission It is greatly diminished in cases of sprue in relapse The absence of proteolytic activity in cases of pernicious anemia suggests that the deficiency of intrinsic factor so characteristic of pernicious anemia, may be present in sprue in relapse

"3 In two non-anemic normal subjects, it appears that infection inhibited this type of proteolysis to a considerable degree "

HAEMATOLOGY

SPIES, T D, GARCIA LOPEZ, G, MILANES, F, STONE, R. E, LOPEZ TOCA, R, ARAMBURU, T & KARTUS, S Observations on the Effect of an Animal Protein Factor Concentrate on Persons with the Macrocytic Anemia of Pernicious Anemia, of Nutritional Macrocytic Anemia and of Sprue, and on Persons with Nutritional Glossitis *Blood* 1949, July, v 4, No 7, 819-26, 4 figs [18 refs]

"The intramuscular injection of animal protein factor concentrate to 5 cases of pernicious anemia in relapse, 4 cases of nutritional macrocytic anemia in

relapse and 3 cases of tropical sprue in relapse was followed by a positive hematologic response in each case as is illustrated in figures 1, 2, and 4 respectively. The parenteral administration of this material to 3 patients with nutritional glossitis unassociated with anaemia was followed by the disappearance of the redness and soreness of the tongue."

SEITALA, A. Studies on the Haemoglobin Values of the Blood and on Anaemia in the Population of the Kärkölä District. *Ann 3rd Intern Fenniae* Helsinki, 1949 v 28, Suppl. 4 52 pp. 4 figs. 82 refs.]

Haemoglobin determinations were made on 4 075 persons of Kärkölä district of Finland—this number constituted 70 per cent. of the population.

Four cases of frank *Diphyllobothrium latum* anaemia were excluded, but the series included 177 worm carriers. Analyzed separately these showed the following figures—

	Number	Established mg. haemoglobin per 100 ml.	Deviation from normal value
Men ..	39	15.1	+0.01
Boys ..	19	12.30	+0.14
Women ..	61	11.91	-0.1
Girls ..	11	11.00	-0.09
Total ..	127	12.35	-0.05

The author notes that the effect of the presence of the worm appears to be greater on women than on men.

NEEL, J. V. The Inheritance of Sickle Cell Anemia. *Science*, 1949, July 15 61-6 [16 refs.]

CHEV S. C., FLEMING Eleanor M. & CASTLE W. B. Studies on the Destruction of Red Blood Cells. V. Irreversibly Sickled Erythrocytes: Their Experimental Production in Vitro. *Blood*, 1949 May v 4 No. 5 794-803

In sickle-cell disease when the erythrocytes are deprived of oxygen they tend to assume a sickle or oval shape but when they are again exposed to oxygen the majority reassume their normal discoid shape. A certain number however do not recover their normal shape. These irreversibly sick cells differ from the others in showing no filamentous processes. The factors that cause this irreversibility were studied in a series of experiments with the blood of four patients with sickle-cell disease.

After the erythrocytes of these 4 patients had been kept for 24 hours at 37°C. in the absence of oxygen, they were then exposed to oxygen. The cells which had been kept in the absence of oxygen for 24 hours and then exposed to oxygen largely retained this ability to revert to the discoid form when exposed to oxygen. The cells which had been kept in the absence of oxygen for 48 hours and then exposed to oxygen largely retained this ability.

The studies confirmed the hypothesis that frequent stagnation of the red cells in the tissues with subsequent sickling eventually leads to the production of irreversible sickled forms

The fact that sickled reticulocytes are seldom seen in blood films is accounted for by the observation that these young cells do not readily acquire the irreversible sickling property

L E Napier

PRATT-THOMAS, H R & SWITZER, P K *Sicklemlia its Pathological and Clinical Significance* *Southern Med J* 1949, May, v 42, No 5, 376-83, 9 figs [14 refs]

In a series of 2,008 necropsies on negroes in South Carolina, some form of sickle-cell disease was demonstrated in 115 (5.72 per cent), in 23 (1.14 per cent) of these there was sickle-cell anaemia

"While sicklemlia need not be clinically significant and does not necessarily predicate a shortened life, it is believed that at times it is responsible for lesions and untoward results occurring in those states which produce a lowering of oxygen tension"

Any conditions causing shock, traumatic or otherwise, and prolonged general anaesthesia are liable to produce a general anoxaemia which results in an increase of sickling of erythrocytes accompanied by an increase in their viscosity. This causes localized agglutinations of erythrocytes which produce obstruction and infection without necessarily thrombosis, the authors believe that thrombus formation is actually the exception rather than the rule. Thus localized agglutination causes local anoxia, damage to the vessel walls, transudation of fluid and haemo-concentration. A vicious circle is thus established which could only be reversed by oxygenation of the erythrocytes so that they recover their discoid shape

The authors give a number of examples of patients who showed no evidence of sickle-cell anaemia but in whom death, usually after operations, was due to widespread vascular obstruction and others in which this was probably an important contributory cause of death

In the discussion on this paper, Dr Paul Kummelstiel questions whether the "conglutination" of the red cells could be the primary cause since he cannot conceive that such a condition could be reversible. He believes that vascular spasm is the first event and that the conglutinations are secondary. In such circumstances relaxation of the vascular spasm could cause a reversal of the condition

L E Napier

FADEN, R S *Ovalocytosis associated with the Sickle Cell Trait* *Blood* 1949, May, v 4, No 5, 505-10, 3 figs [13 refs]

A case is reported in which a negro's blood showed both the sickle cell trait and ovalocytosis. In the peripheral blood the percentage of sickled cells varied from 3 to 11 and the percentage of ovalocytes from 65 to 84

In the only previously reported case of this nature, some of the oval cells showed the sickling property, but in the present case in a sealed wet preparation only the normal, discoid cells sickled in 18 hours, the ovalocytes underwent no change in 72 hours, and there was no increase in the numbers within this period. The blood picture was otherwise within the normal limits, except that there was an increased resistance to hypotonic saline solutions

KAPLAN E. & LEWIN S. R. The Effect of Human Plasma Transfusions on the Fetal Urobilinogen Excretion in Sickle Cell Anemia. *Blood* 1949 Aug. v 4 No. 8 847-57 5 figs. [10 refs.]

"1 The results of transfusion of whole plasma and blood on the fetal urobilinogen excretion of 5 children with sickle cell anemia have been reported.

"2 The phenomenon observed by Joseph—a reduction in urobilinogen output following plasma transfusions—has been confirmed.

"3 It has been observed further that in certain patients the continued use of plasma transfusions induces a reversal of this phenomenon, namely an increase in urobilinogen output after each transfusion.

"4 The possible significance of these phenomena is discussed and attention is called to the limitations inherent in accepting urobilinogen excretion as a valid index of hemoglobin destruction in certain disorders in which a defect of hemoglobin metabolism may be present."

VENOMS AND ANTIVENENES

STANIĆ M. Acquired and Experimental Hypersensitiveness to Man and Animal from the Venom of the *Vipera ammodytes*. *Acta Med 1 generica* 1949 v 3 No. 1 1-8, 6 charts

PHILPOT V. B. Jr. Influence of Snake Venom on Mammalian Erythrocytes in Vitro. *Amer J Physiol* 1949 July 1 134, No. 1 7-32. [10 refs.]

"Water moccasin and copperhead venoms bring about agglutination and subsequent hemolysis of washed human erythrocytes. The venom of the rattlesnake *C. adamanteus* also hemolyzes washed human erythrocytes, but not to the same degree as occurs with water moccasin and copperhead venoms. Human serum inhibits the hemolytic activity of the 3 venoms on human cells. Serum of the dog and sheep activates the action of water moccasin venom on their homologous erythrocytes whereas serum of the rabbit and man act as an inhibitor. Dog cells in the presence of serum are much more susceptible to the action of rattlesnake venom than are human cells. Fresh dog serum heated dog serum and rabbit serum will activate rattlesnake venom hemolysis of dog cells.

MACKENROY J. E. Breve revista sobre 1 rashmo cutaneo-gangrenoso y hemolitico en el Uruguay. A Note on Gangrene of the Skin and Hemolysis caused by the Bite of Spiders in Uruguay. *Arch Uruguays de Med. Ciruj. y Especialidade* 1948 Nov-Dec 33 Nov 56 173 7

The English summary appended to the paper is as follows:—

Brief review about gangrene of the skin hemolysis and local necrosis produced by the bite of spiders.

One spider was captured and classified—the genus *Loxosceles*.

"General symptoms may be severe and death is not rare but usually the general symptoms last a few days evolution during 5 days.

"An improvement is observed usually during the 5th day but it is more remarkable during the 6th day. Nevertheless local symptoms last for several weeks.

DERMATOLOGY AND FUNGUS DISEASES

GREENWOOD, K Common Skin Disorders of the Army in the Tropics J Roy Army Med Corps 1949, June, v 92 No 6, 284-9

This article consists of a survey of the commoner dermatological problems encountered at the Military Hospital, Singapore Fungus infections were exceedingly common and accounted for 20 per cent of all out-patients and 28 per cent of inpatients The most common fungus found was *Trichophyton mentagrophytes* which the author considered to be a variant of *Trichophyton interdigitale* The author did not believe this to be indigenous to Malaya but considered that it was imported on the feet of the European soldier Other species of fungus found were *Trichophyton interdigitale*, *Epidermophyton floccosum*, and *Trichophyton rubrum*

On the face a typical ringed lesion might be found, more commonly however tinea barbae presented with deep seated pustular lesions over the beard area, and the subsequent development of abscesses which sometimes reached considerable size This is the condition known as Kerion

On the feet an interdigital fungus might present as an area of redness, scaling and maceration or, as typical rings of vesicles or broken vesicles The author emphasizes that the vesicle was a non-specific reaction to various aetiological agents It might result from fungus infection in which case it could be cleared with fungicides or it might develop as a reaction to over-treatment If more fungicides were applied to the latter condition it would be aggravated Pompholyx was frequently encountered, appearing sometimes as a secondary reaction to an interdigital fungus infection, and sometimes as a non-specific eczematous eruption

Prophylactic treatment of fungus infection was of the greatest importance, every officer should be capable of looking at the skin for obvious lesions, and examining toe-clefts for early signs A useful prophylactic paint was

Brilliant green	1 0
Hydrarg perchlor	0 1
70 per cent spirit ad	100 0

For curative treatment, various fungicides were effective such as 2 per cent chrysarobin in Lassar's paste, Whitfield's ointment and lotion, and Castellani's paint The undecylenates and propionates did not appear strong enough to control infection

Other conditions encountered were contact dermatitis and dermatitis medicamentosa These were no less common in Malaya than elsewhere Sensitivity to oil resulting in a vesicular eruption of the fingers, and dermatitis on the waist, thighs and buttocks as a result of sensitivity to green uniform were two conditions of frequent occurrence

While mild cases of acne improved especially after exposure to sunlight, severe pustular acne did badly and men with this condition should not be sent out Prickly heat responded to light airy clothing, sun bathing and sufficient baths to maintain cleanliness but no more Soaps used should be of the blandest possible kind In treatment, a 10 per cent salicylic acid lotion could be used cautiously The author concludes his article with the following useful hints —Bullous impetigo was very common and could be treated with any mild antiseptic

Scabies must be treated first, then the secondary infection, chronic urticaria sometimes resulted from helminth infection The diphtheria bacillus was an occasional cause of tropical ulcer The depigmented patches on Malays were due to pityriasis versicolor and responded to any fungicide

H T H Wilson

SIMONS, R. D. G. Is *Tinea albigena* Nieuwenhuis a Separate Disease or an Indonesian Pinta combined with Epidermophytosis? *Documenta Neerlandica et Indonitica et Malaria Tropica*: Amsterdam, 1949 June v. 1 No. 2, 182-93 14 figs. 17 refs.]

Nieuwenhuis in 1903 described a form of mycosis involving mainly and almost exclusively the hands and feet. He found in association with the lesions a fungus which he grew and considered a *Trichophyton*. Though in respect of depigmentation it resembled *mal del pinto* in certain points it was, he said, to be differentiated by the fact that *mal del pinto* never invades the palms or soles. Nieuwenhuis named the fungus *Trichophyton albigena* s. Later in 1925 OTA transferred it to the genus *Ctenospora* and 10 years later still Dorcex called it *Aletrisima albigena* s.

Nieuwenhuis described the disease as having two stages: papules and vesicles in the first stage and, years afterwards, depigmentation. At this time fungi were being recorded as being associated with and the cause of pinta. But—and this is very important—pinta has since been proved to be due to a spirochaete and the fungi were chance concomitants, and also pinta may affect the hands and feet. The author gives brief notes of two cases, one of *melung* (pinta) and one of "*Tinea albigena*" (Nieuwenhuis's *Trichophyton albigena* s).

Very clear photographs illustrate this article and the discussion is full of interest and cannot be summed up better than in the author's own words in which he says he is led to conclude that—

"(1) NIEUWENHUIS was mistaken in separating *tinea albigena* from pinta on the strength of the assertion that pinta does not invade the palms of the hands or the soles of the feet.

"(2) He demonstrated fungi that (a) are not specific, (b) are also found in epidermophytosis.

"(3) He described pleomorphism as a characteristic feature in a number of cases.

"(4) His picture of *tinea albigena* represented pinta or pintoïd framboesia in some instances this disease may be clearly recognized.

"(5) His experiments with inoculation did not constitute proof. It was also unable to induce discolouration.

"(6) He found fungi that were isolated from vesicles on the soles of the feet and around which no achromas had generally occurred.

"(7) *ZIEGLER*'s *melung* was never conclusively separated from pinta, its symptoms were identical with those of pinta, according to *ZIEGLER*'s description.

"(8) The same holds good for *JEANSEUNE*'s *khj huen*, which was also considered to be *tinea albigena*.

"(9) Nowhere in the literature can NIEUWENHUIS' findings be confirmed, but his false differential diagnosis has always been copied.

"(10) In my opinion the different names of the fungi being in vogue by present have terminological significance only. H. Harold Scott

LEITE, A. S., DA LUZ, J. V. B. & DE MEIRA, M. T. V. ("mosy foot" in Africa. *Am. Inst. Med. Trop.* Lisbon, 1948, Dec v. 5 7-30 11 figs. on 4 pls. 39 refs. English summary

In an expedition to Angola in 1945 the authors saw several cases of what is generally known as mosy foot first described by Wolterstan Thomas in 1910. They refer to the various accounts in the literature describing verrucous conditions of the feet and legs to *Acrotheca*, *Phallophora*, *Hormodendron*

Fonsecaea and other fungi, and describe the lesions in the various stages in detail. These need not be stated here, the appearance is well known to readers of the *Bulletin*. The most interesting part of this contribution is that dealing with the diagnosis, for it shows that "mossy foot" is a generic rather than a specific term and covers—at all events has covered—a number of really different conditions. Among these are dermatitis verrucosa and forms of chromoblastomycosis, Madura foot, leishmaniasis, leprosy and elephantiasis and others less likely to be confused, such as syphilis, verruca peruviana and yaws.

The authors put forward the view that the cause may be a streptococcus which has gained entrance through some surface wound and that the inflammatory, hypertrophic and other changes are secondary to this, by setting up lymphatic obstruction and repeated "inflammatory crises."

Modes of treatment have been many: radiotherapy, thermocautery, elastic compression, chemotherapy with arsenicals, iodides, bismuth, acriflavin and potassium permanganate, but until more research has been carried out to determine the actual cause and to separate the various conditions included under the term mossy foot, the treatment must be largely empirical. The article is embellished with good photographs of the clinical condition and photomicrographs of the histological changes. *H Harold Scott*

CRAWLEY, E. P. Sporotrichosis, a Protean Disease with Report of a Disseminated Subcutaneous Gummatous Case of the Disease. *Ann Intern Med* 1949, June, v 30, No 6, 1287-94, 6 figs [10 refs]

A case of the rare disseminated subcutaneous form of sporotrichosis is described. The patient, a man aged 70, had suffered from a generalized papular, gummatous and ulcerative eruption on the skin for several weeks. The first lesion noticed was an erythematous papule, situated on the lower part of the back, which softened and ulcerated within a few days. This was followed quickly by the appearance of similar papules on the right thigh and right temporal region, and very soon by a generalized eruption affecting the face and neck, trunk and extremities. The lesions were indolent, discrete and polymorphic, varying from the size of a match-head to a cherry. They commenced as firm erythematous papules which later underwent central softening, broke down and discharged their purulent contents, leaving a central crateriform ulcer with firm indurated margins. Some of the lesions were in process of healing. In addition to the skin lesions, the proximal phalanx of the right great toe and of the left fourth finger as well as the middle phalanx of the right fourth finger were swollen and inflamed, and radiography showed an underlying osteomyelitis. Despite the large number of lesions the patient's general health appeared to be unaffected and the only subjective symptom was pruritus.

Sporotrichum schenckii was isolated in culture from the lesions, although it was not found by microscopical examination of smears and sections. Prolonged and intensive treatment with potassium iodide brought about complete resolution of the lesions including those of the small bones of the hand and foot.

KIRSCH, E. Die Histoplasmose. Eine Uebersicht. [*Histoplasmosis a Review*] *Ztschr f Tropenmed u Parasit* Stuttgart 1949, Aug, v 1, No 2, 287-300, 3 figs [69 refs]

A general account

EMMONS C. W. Isolation of *Histoplasma capsulatum* from Soil. *Pub Health Rep. Wash.* 1949 July 13 v 64 No. 23, 267-8 17 figs. [15 refs.]

Although histoplasmosis was discovered by DARTING more than 40 years ago its epidemiology is still imperfectly known. The disease occurs in men and dogs and recently EMMONS *et al* [this Bulletin 1948, v 45 207] found it in the rat and mouse on a farmstead in Loudoun County, Virginia, where human and canine cases of histoplasmosis had occurred. Like other systemic mycoses caused by dimorphic fungi, histoplasmosis is not transmitted from host to host but infection is presumed to be caused by spores of the saprophytic form of the fungus vegetating in nature. Up to the publication of the present paper no report of the discovery of the saprophytic form of the fungus vegetating under natural conditions had been made.

EMMONS, applying the methods which he used so successfully in his epidemiological study of coccidioidomycosis (*Pub. Health Rep.* 1942, v 57 1049) examined 387 samples of soil taken from the farmstead referred to above and succeeded in isolating *H. capsulatum* from two. The fungus was isolated by inoculating the soil washings intraperitoneally into mice and making cultures from the liver and spleen of the animals which were killed from 3 to 5 weeks after the date of inoculation. Direct cultivation from the soil was impracticable because of the number of contaminating micro-organisms, but microscopic examination of the washings of the two infected soil samples showed the characteristic tuberculated macroconidia of the saprophytic form of *H. capsulatum*.

A. The two significant samples had been taken from the same mass of red earth apparently removed from rat burrows. It may be contended that they were merely contaminated by infected animals, but the discovery of the characteristic macroconidia showed that the fungus had vegetated saprophytically on the soil and indicated that the parasite can complete its developmental cycle in this environment.

TAYLOR A. B. & BRIKEY A. K. Observations on Primary Coccidioidomycosis. *Ann Intern. Med.* 1949 June v 30 No. 6 1224-31 5 figs. & 1 chart [18 refs.]

Much of the ground covered by the authors has been dealt with in earlier papers by GOLDSTEIN & LOVIE (*Bulletin of Hygiene* 1944 v 19 774), GOLDSTEIN & McDONALD (*ibid* 770), WILLETT & WEISS (1945) and SMITH *et al* (1946) [this Bulletin 1946, v 43 857, 1947 v 44 675].

Forty-three proved cases of primary coccidioidomycosis which included 39 males (7 were Negroes and 1 a Filipino) and 4 females were studied clinically and followed-up after convalescence. The following symptoms were recorded: Chest pain (90 per cent. of the patients) was usually substernal and not sharply localized. It was aggravated by deep respiration and by coughing, but no matter how severe it may have been it invariably subsided after two days rest in bed. Cough (44 per cent.) was usually nonproductive and tended to disappear after a few days rest. Blood-streaked sputum was rarely seen. Malaise was a prominent symptom in 32 per cent. of the patients, but probably all patients suffer from it to some extent. It was the most persistent of the symptoms. Fever and chills (30 per cent.) ceased after a day or two in bed. The fever was usually of a low grade and the highest temperature recorded was 103°F. Headache of a generalized type was complained of by 28 per cent. of patients. Dyspnea associated with substernal pain occurred in 25 per cent. and, although relatively infrequent, it was one of the most characteristic symptoms. It was probably due to extensive hilar adenitis or low grade

mediastinitis. Abdominal pain, simulating gall bladder colic was present in two cases and was due to infiltration of the lung over the right dome of the diaphragm. Erythema nodosum occurred in 4 patients and erythema multiforme in 2. The coccidioidin test gave a positive result in all cases, and in 11 the reaction was intense. The highest initial red blood cell sedimentation rate was 51 mm per hour and the average rate 32 mm per hour. The prognostic value of serological tests was not investigated.

Radiological examination of the chest showed the following types of lesion: *Diffuse pneumonia-like infiltrations*, in 83 per cent of the cases. These were usually isolated, peripheral and lobular, well circumscribed and of homogeneous density. They were usually accompanied by increased hilar shadows and sometimes by definite hilar adenopathy. Complete resolution of the peripheral infiltrations occurred in from 5 days to 3 months in some cases but in others they persisted up to 10 months and left a discrete fibrous nodule at the site of infiltration. Lesions in the lung apices simulated active reinfection tuberculosis. *Nodular parenchymal lesions*, said to be the most characteristic finding in the primary disease, were the discrete fibrous nodules representing incomplete resolution of previous infiltrations, usually of the lobular type. They averaged 2 cm in diameter, were single, isolated, well circumscribed and showed no evidence of calcification. They were equally distributed over upper and lower lobes. *Cavitation* occurred in lung nodules in two patients, in one case taking 11 days and in the other 8 months to become apparent. The cavities remained static for 5 to 10 months and were marked by their thin wall, the absence of a surrounding inflammatory reaction and their situation in the upper lobe. *Pleural effusion* occurred in 3 cases in association with parenchymal infiltrations. A minimal effusion was absorbed in 3 days and a massive one in 3 weeks.

Treatment consisted of rest in bed and treatment of symptoms.

Chemotherapy was not employed. An outstanding feature of this disease was the almost universal feeling of well-being which made the patient reluctant to accept the necessary rest treatment. J T Duncan

RITTER, F H. Tumor cerebral granulomatoso por paracoccidioides a propósito de dois casos operados. [Two Cases of Granulomatous Brain Tumour operated upon and shown to be due to *Paracoccidioides brasiliensis*] *Arquivos de Neuro-Psiquiatria* S Paulo 1948, Dec, v 6, No 4, 352-9

The English summary appended to the paper is as follows —

The author presents two cases operated on of granulomatous cerebral tumor—one of the cerebral hemisphere, and the other from the cerebellum—caused by *Paracoccidioides brasiliensis*. In both cases the preoperative diagnosis had been of brain tumor, probably glioma. Nothing in the anamnesis nor in the neurological examination gave any hints of the real cause of the disease. Even though probably rare, the solitary cerebral micomas deserve consideration when making a neurosurgical differential diagnosis in our country."

TROPICAL OPHTHALMOLOGY

TURTZ, C A. Solar Burns of Fundi. *New York State J of Med* 1948, Nov 15, v 48, 2489 [Summary taken from *J Amer Med Ass* 1949, Apr 2, v 139, No 14, 962]

Turtz observed 5 cases of burns of the retina during the past four years. Three were seen within a few days after exposure to strong sunlight. The

other 2 were seen four to six hours after exposure to sun lamps. All 3 complained of pain, photophobia and lacrimation, and all had conjunctival injection to a varying degree several hours after exposure. An early examination with the ophthalmoscope may reveal nothing pathologic or a pale spot surrounded by a brownish ring, may be seen at the fovea. Later there may be pigment deposits and a small gray punctate spot around the fovea, and this may be replaced by a hole. The prognosis should be guarded. Even though improvement may occur a positive scotoma with permanent impairment in vision usually results. The public should be enlightened as to the dangers of prolonged exposure to sunlight and the careless use of sunlamp treatments without adequate protection to the eyes.

RISQUEZ IRIBARREN R., CORDERO MORENO R. & ANDRUE J. J.
Consideraciones generales acerca de la conjuntivitis epidémica [Reflections on Epidemic Conjunctivitis.] *Rev. Med. Caracas*. 1949 Jan. v 1 No. 1. 109-23 1 map. 24 refs. English summary

In parts of Western Venezuela, notably Dabajuro Maracaibo and, further east San Felipe Chiracón and Acarigua outbreaks of conjunctivitis occurred, usually of a mild character and clearing up spontaneously. Occasionally there would be phlyctenules and corneal ulcers or some superficial punctate keratitis. The outbreaks would coincide with the early rain and a temporary abundance of mosquitoes. Cases both in 1947 and 1948, were $2\frac{1}{2}$ to 3 times as numerous in the second half of the year, that is the rainy period.

The authors discuss whether this is the same as the epidemic kerato-conjunctivitis as has been reported from the United States and due to a virus but apparently no investigations have been undertaken to confirm or refute this hypothesis. Common insects and possible vectors are *Hippelates flaviceps*, *H. depressus* and *S. plumbeus signatus*. These frequent excreta and release dumps and in the places where the outbreaks occurred sanitation is said to be primitive. The Koch-Weeks organism has been found in 40 out of 50 cases examined. (Not a very satisfactory paper. It consists of general remarks on a condition whose aetiology can be decided only by intensive laboratory studies which could not be—at all events were not—undertaken in these cases.)

|| || || ||

SARKIS L. T. Melanoderma humana e tracoma. [Melanoderma and Trachoma in Man.] *Rev. d. Biol. Colomb.* 1947 8 117-31. Ref. 5 footnotes

The author refers in general terms—no figures are given—to various places and people over the globe and puts forward the thesis that the degree of colour in the skin is protective against trachoma: the darker the skin the less prevalent is trachoma among them.

If there is anything to this theory more detailed investigation and critical studies will doubtless be undertaken to support or refute it.

MOCTINO R., GILLO M. & DE MORA, S. Trucomas e trachoma de tratamento com aureomicina. First Trials of Aureomycin in the Treatment of Trachoma. *Rev. Med. Portuguesa* 1949 2 No. 2 497-503. English summary

The authors first tried an aqueous solution of urea in relation to the borate and chlorid of sodium but these proved very unsatisfactory. Their activity in 48 hours even though kept in an ice-chest. They then forewent

to make a fatty preparation whose effect could be aided by a massaging action through the eyelids. Aureomycin as a powder is quite stable and they obtained an anhydrous neutral excipient (pH 7.7) made up of equal parts of aureomycin hydrochloride and pure sodium borate, 25 mgm in each 5 gm of the ointment. This was applied every 3-4 hours for 2-10 days. Administration *per os* of aureomycin combined with the ointment locally "seems very favourable" and was well tolerated in a dose of 25 cgm every 3 hours, or 50 cgm every 6 hours. A table gives details of 15 patients in stages I to IV of the disease, their sex, age, condition before treatment was begun, the duration of the treatment and the results, with a column for remarks. With one exception the longest time of treatment was 8 days and some showed amelioration in 48 hours or even less. In brief, the results were most encouraging.

H Harold Scott

TROPICAL ULCER

GORDZIALKOWSKI, H Contribution to the Therapy of Tropical Ulcer. *Bull. Inst Marine & Trop Med, Med Acad Gdansk, Poland* 1948, v 1, No 1, 17-22

This paper is a summary, from memory, of work carried out for three years before the war in the Belgian Congo. The author's records were subsequently lost as a result of enemy action. He now points out that since he devised his method, great chemotherapeutic studies have been made but he feels that it is worthy of record owing to its simplicity and cheapness.

He considers that pure crystalline boric acid has a strong germicidal action, without destroying the tissues. After curettage of necrotic masses, the ulcer is liberally covered with the crystalline boric acid daily for three days or longer if required. Usually (except in very refractory cases requiring repeated curettage or cauterization) the ulcer was almost dry and beginning granulation on the fourth day. At this stage, spirochaetes and fusiform bacteria were absent.

Thereafter an ointment was applied, at first daily, and subsequently every other day or third day. This consisted of —

Zinc oxide	100 gm
Dermatol [Bismuth oxygallate]	100 gm
Balsam of Peru	50 gm
Vaseline	100 gm
Lanoline	50 gm
Liquid vaseline to make a paste	

This is applied in a fairly thick layer and it is claimed that it produces a rapid epidermization. Complete healing of an ulcer of 5 cm diameter occurred in 3 to 4 weeks and smaller ones healed in 2 or 3 weeks.

A description is given of a severe chronic case which eventually responded to this treatment after several months during which other forms of treatment had failed.

After several months of this treatment, the number of patients in ulcer wards in the author's hospital was halved and their average stay in hospital shortened to about one-third. The application of boric acid was usually completely painless, but occasionally was very slightly painful. Crystalline boric acid was found to exert "an incomparably better action than powdered boric acid."

Later in Poland during the war the author used boric acid in non-specific ulcers. It was quite ineffectively and occasionally even harmful but the ointment was often useful. It is therefore suggested that the boric acid has some specific effect on tropical ulcer possibly because the slightly increased acidity is unfavourable to the life and growth of specific microbes, in this case presumably spirochaetes and fusiform bacteria.

H. J. O'D. Burke-Gaffney

MISCELLANEOUS DISEASES

CARRILLO E. G. Some Cardiological Problems of the Tropics. *Amer. J. Med. Sci.* 1949 June v 717 No 6 619-26. [39 refs.]

The author has analysed 8,000 autopsies at San Juan de Dios Hospital in Costa Rica and finds that cardiovascular disease accounted for 768 deaths (9.6 per cent). The quinquennial mortality rate from this cause has risen—as it has in every country in which statistics are kept—between 1916 and 1940 by nearly 50 per cent from 84.7 to 122.3 per 100,000 inhabitants.

After remarks on the physical geography of Costa Rica, the author considers the question of heart disease under three heads: 1. The frequent causes. 2. The rarer causes. 3. The heart in relation to some tropical diseases. In the first, atherosclerosis heads the list with 4.4 per cent of all autopsies and 48.1 per cent of cardiac deaths; rheumatism coming next with 20 per cent of cardiac deaths; syphilis follows closely with 19.1 but if negroes are excluded from the list the percentage is only 13. Coronary disease is relatively rare and this is attributed by the author to the diet being deficient in fats. Among the rarer causes are mentioned pericarditis, myocardial infarction and cysticercosis of the myocardium. Acute bacterial endocarditis was seen on two occasions only but there were 19 of the subacute variety: nothing is said of the causative organism! In his remarks on the heart in relation to some tropical diseases the author says that although Chagas's disease is seen in Costa Rica he has not come across a case among the 8,000 autopsies. Ankylostomiasis is very common and the anaemia resulting therefrom may account for some of the deaths from pulmonary embolism. Ten deaths were due to bites by *Bothrops atrox* and *B. schlegelii* and in these patients there were sub-endocardial and epicardial petechial haemorrhages. In such patients during life the electrocardiograms showed a low amplitude T wave and slight depression of the ST junction in precordial lead CR5 with prolonged QT but only in those showing toxic symptoms. These changes have been found in post-viraemia and it is thought that they may be due to this cause in these patients. *H. Harold Scott*

JELLINEF D. B. Splenic Abscess in the Tropics. *J. T. P. M. J. & H. C.* 1949 July v 52, No 7 131-40 3 figs. 3 refs.

Splenic abscess may be primary, though discussible, or secondary in which the aetiology is known. The latter group may be (a) embolic (1) traumatic or (2) due to direct infection from a suppurating focus. (a) *Embolic*—The infection is carried to the spleen via the portal system as an ascending pylophlebitis with thrombosis of the plexus, or as a result of intra-abdominal suppuration. Splenic infarction is not usually recognized until revealed by autopsy. Alternatively the spleen may be infected through the systemic arteries from a primary focus elsewhere, sometimes appearing months after the original lesion has settled down. In the tropics the typhoid group of

fevers is an important factor in the aetiology and the latent period before the appearance of the abscess may be very long, 19 years has been recorded. Amoebic abscess of the spleen may be solitary or associated with hepatic abscess, infection may be *via* the portal system or direct from an adherent infected splenic flexure, it manifests itself by a high swinging temperature, tender, enlarged spleen and leucocytosis. Aspiration produces sterile anchovy-sauce pus in which amoebae are not usually found, improvement is rapid with emetine. Abscess of the spleen may occur in relapsing fever from infarction of splenic arterioles, in Egypt, EL-RAMLY [this *Bulletin*, 1948, v 45, 185] found of the spleen in 20 per cent of 139 fatal cases of relapsing fever and abscess of the spleen in 11.5 per cent. Recently L. A. NASR [*ibid*, 604] recorded seven cases occurring two or three weeks after relapsing fever, successfully treated by drainage. (b) *Traumatic* cases usually follow non-penetrating injuries with subsequent infection of a haematoma. (c) *Direct infection* may occur from spread of a suppurative process in an adjacent viscus, e.g., leaking gastric ulcer, perinephric abscess, etc. the onset may be sudden or insidious and may be overshadowed by the symptoms of the causative infection. Pain in the left hypochondrium, worse on coughing and radiating to the left side of the chest is the most constant symptom, fever is usually high, but in chronic infections it may be slight. The spleen is enlarged and tender, and in late cases may be adherent, the abscess pointing through the abdominal wall. Physical signs in the chest, pleural effusion and raising of the diaphragm with displacement of the heart on radiography are common. Treatment is by aspiration, followed by penicillin, with drainage by the abdominal route if this fails.

Primary abscesses have been reported more frequently from the tropics than elsewhere. WALLACE in N Rhodesia has recorded 49 seen in two years, 19 of these were diagnosed and drained, with an 80 per cent recovery rate. Onset was sudden with fever and rapid enlargement of the spleen, which at operation was found to be adherent to the abdominal wall. The abscess cavity contained gas and up to eight pints of pus, usually sterile, and no amoebae were found. Laboratory examinations were negative for typhoid, undulant fever and syphilis. Thrombophlebitis of the leg veins developed later in a high percentage of cases, sometimes associated with intestinal thrombosis. Cases have been reported from other parts of the tropics. Two cases which were successfully treated are described. The author considers that the most probable aetiology is slight injury to a spleen already enlarged and vascular from malaria or other cause, producing subcapsular haemorrhage, which later becomes infected. Thrombosis of the splenic vein producing colliquative necrosis is probably an important factor in some cases.

W L Harnett

CRUICKSHANK, J C. **Failure of Aureomycin in Experimental Mollidosis** *Brit Med J* 1949, Aug 20, 410-11

Generalized melioidosis is almost invariably fatal, and recovery usually occurs only in those cases with localized superficial abscesses. Although no satisfactory therapeutic agent has yet been described, varying degrees of success and failure have been reported with certain sulphonamides and antibiotics. chloromycetin (chloraphenicol) has been shown to be highly inhibitory to *Pf whittmorei in vitro*. The author discusses these various reports, as summarized by GREEN and MANKIKAR [this *Bulletin*, 1949, v 46, 498] and then describes a small laboratory trial of aureomycin in the experimental treatment of the disease.

Tests of the inhibitory action of aureomycin *in vitro* were made after the method of PAINE *et al* [see *Bulletin of Hygiene*, 1949, v 24, 274], and the

technique is described. The final concentration of aureomycin ranged from 100 to 0.4 $\mu\text{gm.}$ per ml. Strains of *Str. pyogenes* and faecal *Bact. col.* were tested in parallel. A table shows the results, which indicate that *Pf. whitmorei* was inhibited by 1.5 $\mu\text{gm.}$ per ml. of aureomycin in broth and by 6.3 $\mu\text{gm.}$ per ml. on a plate—its sensitivity was more closely related to that of *Bact. col.* than to that of the haemolytic streptococcus. It is pointed out that levels up to 2 $\mu\text{gm.}$ per ml. may be obtained in the blood four hours after a single oral dose of 500 mgm. in healthy persons—this falls in 12 hours to about 0.49 $\mu\text{gm.}$ per ml. (see SCHNEIDERSON & TORANSKY *Bulletin of Hygiene* 1949 v. 4 8-9).

A small and rapid preliminary *in vivo* test was then made in guinea-pigs and Professor Cruickshank points out that its limited nature had the advantage of reducing the number of persons exposed to laboratory animals with this reputedly highly dangerous organism. Great care was taken to minimize the hazards.

Nine different infecting doses of *Pf. whitmorei* (from 500 million to 5 organisms) were injected into groups of guinea-pigs, half of which were treated intraperitoneally with aureomycin morning and evening from the time of infection to the end of observation. The dosage varied from 1 to 4 mgm.

The results are shown in a table—the strain was very virulent and death occurred in 4 to 11 days according to the infecting dosage. There was little difference between the treated and control animals, in respect of the typical lesions produced or in the fatal course of the disease—the slightly longer survival time of some of the treated animals was not significant.

The *in vitro* tests did not suggest that larger doses of aureomycin would be likely to be beneficial—and the dosage and spacing actually used conformed with those found effective in other infections, e.g. Weil's disease.

It is evident that aureomycin did not materially influence the course of experimental melioidosis in guinea-pigs. H. J. O'D. Burke-Gaffney

GELFAND M. Some Peculiar Cases of Gangrene and their possible relationship to Tropical Phlebitis. *Trans. Roy. Soc. Trop. Med. & Hyg.* 1949 July v. 43 No. 1 75-8, 9 coloured pls.

Gelfand has already shown this *Bulletin* 1949 48 575 that tropical phlebitis there may be a simultaneous spasm of the artery or arterioles corresponding to the affected vein which is an essential part of the cause of the oedema which accompanies the phlebitis. He found that this oedema disappeared if the influence of the sympathetic nervous system in the arteries was eliminated by local injections of procaine. He now reports two cases of gangrene of the fingers following pain and swelling in which the lesion was probably a primary phlebitis with associated arteriole spasm. In both the radial artery could not be palpated though the brachial artery was pulsating normally. The patients were Africans aged 44 and 15 years respectively and were otherwise healthy.

As an illustration of the fact that thrombophlebitis complicating acute infections may also lead to gangrene the author quotes the case of an African child with pneumonia and gangrene of one foot. The gangrene in this case could best be explained as due to thrombophlebitis with arterial spasm for the arteries of the affected foot could not be felt though the popliteal artery was pulsating. The first two cases were probably of primary phlebitis, the last was most probably secondary. C. H. B. Brooks

ANGRISANI, V Cinque casi di Ainhum riscontrati sul Gebel Nefusa
Considerazioni sulla etiopatogenesi dell' "Ainhum" vero e proprio
[The Aetiology of Ainhum Five Cases seen in Gebel Nefusa (Tripolitania)]
Boll Sanitario d Tripolitania 1949, Apr-June, v 7, No 2, 17-22, 2 figs
English summary

The author has seen five cases of ainhum in one district of Tripolitania in a single year, three in adult male arabs and two in immigrants from Fezzan, one of them an elderly woman (? 67 years) The last is reported in detail, but it was quite typical and need not be repeated here The author then tells how writers of a long time ago used to speak of syphilis or leprosy or yaws or syringomyelia as causes of the condition and, later, of ainhum as occurring in, though not aetiologically connected with, syphilis, leprosy, etc He considers each of these in turn and concludes that any slight trauma may initiate the lesion and subsequent inflammation of low-grade result in the formation of a constricting fibrous band or ring which cuts off the nervous and vascular supply until the tissues are destroyed and that ainhum is just a fortuitous surgical condition in countries where the inhabitants go about barefoot *H Harold Scott*

FLOCH, H & DE LAJUDIE, P Pseudo-myiase rampante en Guyane Française
[Creeping Eruption in French Guiana.] Institut Pasteur de la Guyane et
du Territoire de l'Inini Publication No 134 1946, Sept, 4 pp [22 refs]

The authors have already reported three cases of creeping eruption in French Guiana and they now report three more, seen in 1945

The first, in a boy of 14, was on the inner surface of the left knee, the second, in an adult, on the right palm and wrist, and the third, in a European adult, over the left internal malleolus No causative parasite could be found by dissection

The authors discuss the literature and principal features of creeping eruption at some length *H J O'D Burke-Gaffney*

HORTON, S H, Jr Creeping Eruption Report of a Case with Loeffler's
Syndrome U S Nav Med Bull 1949, July-Aug, v 49, No 4, 703-6,
5 figs

"1 A case of creeping eruption with associated Loeffler's syndrome is reported

"2 The larvae were effectively eradicated with fuadin and ethyl chloride spray

"3 In all cases of creeping eruption serial roentgenograms of the chest should be taken as this is the only means of confirming the transient pulmonary infiltrations"

ENTOMOLOGY AND INSECTICIDES GENERAL

DONOSO BARROS, R Un caso de myiasis digestiva en Chile Consideraciones
sobre una nueva etiología, *Lucilia Caesar* (Linnaeus) 1758 (Nov Sp in
Fauna Chilensis) [A Case of Intestinal Myiasis in Chile Notes on *Lucilia*
caesar, a Species New to Chile] Rev Med Chile 1949, Mar, v 77, No 3,
209-11 [12 refs]

The following is a translation of the author's summary —

The author reports for the first time a case of symptomless intestinal myiasis caused by larvae of *Lucilia caesar* (Linnaeus) 1758, a species newly recorded

GEIGY, R. L'hypertrophie parasitaire de la femelle de *Tunga penetrans* [The Hypertrophy of the Female *Tunga penetrans*] *Bull Soc Path Exot.* 1949, v 42, Nos 3/4, 123-5

The author has studied the swelling of the female chigger flea, *Tunga penetrans*, and describes the process step by step. The great expansion of the membrane between the second and third abdominal segments and the lesser expansion of the membrane between the first and second is not a simple dilatation but a multiplication of the cells to accommodate the enlarging intestines and Malpighian tubules. At the same time the powerful muscular system is being adjusted and built up to support these enlarged organs and to counter the pressure provoked by them. Contrary to what was expected, the developing of the ovarioles and the ripening of the eggs does not occur simultaneously with these developments, but forms the second half of the process of enlargement, moreover, the eggs do not develop one at a time as in other fleas but in batches of seven to ten, all the eggs in one lot maturing together. *H S Leeson*

BUTTNER, A. Refixation accidentelle d'un mâle de *Hyalomma excavatum* sur l'homme [Accidental Attachment of a Male *Hyalomma excavatum* to Man] *Ann Parasit Humaine et Comparée* 1949, v 24, Nos 1/2, 186-7

Though ticks of the genus *Hyalomma* are mainly of veterinary interest they have from time to time been recorded on man, but they have commonly been identified as *H. aegyptium*. Laboratory workers have recorded this tick and related species as being capable of causing pathological effects in man, but the author points out that identification of species within this genus presents certain difficulties because of resemblances and variations among them, nevertheless, he wishes to place on record that, in 1948, while engaged in rearing *H. excavatum* on sheep at Richelieu Indre-et-Loire, France he found a male tick on himself and that he tried unsuccessfully to induce other ticks to attach themselves. *H S Leeson*

THÉODORIDÈS, J. Les coléoptères parasites accidentels de l'homme (Note complémentaire) [Coleoptera as Accidental Parasites of Man] *Ann Parasit Humaine et Comparée* 1949, v 24, Nos 1/2, 110-15 [12 refs]

In continuation of his previous paper [this *Bulletin*, 1949, v 46, 785] the author lists eighteen species of beetles or their larvae reported as having been found in the human body or passed out from the intestines. In particular he quotes more records concerning *Tenebrio molitor* and *Blaps mortisaga* and discusses the evidence in one case where a woman was reported to have passed per anum three larvae of *Ptinus tectus*. *H S Leeson*

LABORATORY PROCEDURES

EL HOSNY M. L. A Simple New Stain for Intestinal Protozoa. *J. Roy. Egyptian Med. Soc.* 1949 May v 72, No. 5 428-8.

Quercitrin is a three-sammonose glycoside and is one of the most widely distributed natural pigments. It occurs in many plants, such as horse-chestnut, vine leaves, hops and tea and in the brownish outer skin of the Egyptian onion, *Allium cepa*.

An infusion of this skin, prepared by boiling it until a deep brownish colour is obtained, may be used for staining of intestinal protozoa. It may be used immediately without ripening mordant or differentiating solutions. On storage of the infusion, some sediment occurs but this does not interfere with staining.

Coverslip preparations of infected stool are fixed in Schaudinn's fluid for about 25 minutes and transferred to 70 per cent. alcohol and a little iodine (Weigert Lugol's iodine) for 30-60 minutes. After two changes in pure 70 per cent. alcohol, the slip is transferred to the dye solution which is diluted with 70 per cent. alcohol (staining solution, four parts alcohol, one part dye) for about two hours at 37°C. or preferably overnight. Undiluted stain may be used and staining also occurs at room temperature. The coverslip is then washed in several changes of running tap water left in it for about four minutes dehydrated, cleared and mounted.

It is stated that the stain shows great selectivity and contrast between the cell elements and it is claimed that in selectivity and contrast as a nuclear stain, it gives results equal if not superior to the well known haematoxylin solutions.

H. J. O. D. Burke-Gaffney

REPORTS SURVEYS AND MISCELLANEOUS PAPERS

COLONIAL OFFICE. A Note on some of the Scientific Studies undertaken by Members of the Colonial Medical Service during the Period 1930-47 with a Bibliography Miscellaneous No. 513. 47 pp. 1949 The Church House Westminster S.W.1. Summary appears also in *Bulletin of Hygiene*.

The anonymous author of this note introduces his brief surveys of the various branches of medical enquiry which engaged the attention of the Colonial doctors, by observing that the volume of published papers written by those doctors is 'far from negligible'. This is borne out by the 23 pages of references given to the titles of those papers and the journals in which they were published. 157 of them were published in the *Transactions of the Royal Society of Tropical Medicine and Hygiene* and no less than 494 in the *East African Medical Journal*. At the same time however he makes the important point that most of the records of routine clinical, laboratory and preventive duties are to be found in departmental papers dealing with specific local problems. For instance, some of the most valuable information on trypanosomiasis is to be found in the *Annual Medical Reports of the African territories*. The pioneer work of Dr. G. Mackenzie when he was Sleeping Sickness Officer in Tanganyika Territory is a case in point.

The author also makes the point that laboratory facilities are limited in the tropics (though there are excellent research laboratories at Lagos, Entebbe, Nairobi, Kuala Lumpur and a few other places in addition to the laboratories for routine work in the various countries). This being so much of the work

which required refined techniques has been done outside the Colonies themselves, in laboratories in Britain and elsewhere, and by scientists not members of the Colonial Medical Service, when facilities improve, however, it may be expected that the opportunities for work on the spot will attract research workers to the Service. But laboratory work is not enough, and "the last word must come from the records of happenings in the field", it is in this sphere that so much of the valuable work here recorded has been done. Much of it has been tedious, carried out under difficult physical and mental conditions, in countries where vital statistics as we know them do not exist, and where continued observation of communities is almost impossible in the detail needed for statistical analysis.

The author gives short summaries of the important work done in the period 1930-47, on the following groups of subjects—Nutrition and Deficiency Diseases, Malaria, Trypanosomiasis and Tsetse Flies, Plague, Tuberculosis, Leprosy, Yellow Fever, Rabies, Typhus, Helminthology, Haematology, Blackwater Fever, Neurology and Psychiatry, Pathology, Miscellaneous Studies. These short accounts should be read to be appreciated—they can hardly be condensed.

It would be a mistake to think that the investigations carried out in the Colonies have exclusively concerned the diseases conventionally regarded as tropical. This is by no means the case, and the sections on Nutrition, Tuberculosis, Neurology and Psychiatry, Pathology, and Miscellaneous Studies cover a very wide field. It is well known to those who have served in the tropics that half the troubles are non-tropical, but the tropical diseases have always rewarded research and have usually attracted it rather more than the rest.

A technical point on the bibliography is perhaps worth mention. When two or more authors have published a paper, the full reference will be found under the name of the first author, but not under the names of the others (the bibliography is in alphabetical order of first authors' names). For instance, two papers by OWEN and HENNESSEY are cited under O, but in the list of papers by HENNESSEY (under H) there is no indication that he had collaborated with OWEN, similarly the monograph by POYNTON and HODGKIN is cited under POYNTON but not under HODGKIN, NIVEN's work largely (but not entirely) appears under FIELD and NIVEN. This has the advantage that it does not swell the list by duplication of references, but it has the disadvantage that it is not possible to be sure that all papers published by one person appear in one place. There are certain other features of citation which could be improved.

This modest publication is an account of an impressive amount of good work done in a period which includes the recent war, it is doubtful if any other medical service of comparable size could show a better record.

Charles Wilcocks

BARRETT, R. H. **Health Regulations for Air Travel (III)** *Brit Med J* 1949, Aug 6, 329 [Summary appears also in *Bulletin of Hygiene*]

In October 1948 an Expert Committee on International Epidemiology and Quarantine met in Geneva, and considered a revision of the International Maritime and Aerial Sanitary Conventions, which are to be replaced by WHO Sanitary Regulations. The Committee adopted a liberal attitude, in the direction of relaxation of some of the existing restrictions. Certain principles were proposed on which the WHO Regulations for air travel will be based, as follows—

'1 *Plague and Typhus Inoculations*—These inoculations will not be required of travellers by the new regulations. It was considered by the committee that the use of new insecticides and rodenticides now available should be the most effective method of dealing with outbreaks of these diseases.

2. *Cholera Vaccination*.—This inoculation will not ordinarily be required of travellers but it will be permissible for individual Governments to require it of passengers coming from local areas infected with cholera.

3. *Transit Passengers*.—Air passengers in transit through foreign airports will not be subjected to any sanitary measures in force for that locality—e.g. compulsory inoculations or vaccinations—provided that they are not suffering from an infectious disease and that they do not leave the precinct of the airport. A passenger will not be considered to have left the airport if he is conveyed to another airport in the same vicinity under the supervision of the health authorities.

4. *Immunization of Travellers*.—The committee's views on the subject of immunization of travellers as a quarantine measure are worth quoting at length.

The committee noted that there had developed since the last war a widespread tendency on the part of health administrations to require from travellers certificates of immunization, irrespective of the value of such immunizations for the protection of the countries reached by the travellers or for that of the travellers themselves.

The committee was aware of the many advantages inherent in the compulsory production of immunization certificates, and considered that the serious obstruction to free and rapid travel caused by such requirement was out of all proportion to the protection likely to be afforded to the country of arrival.

5. *The Personal Declaration of Health*.—This document was compulsory for air travellers in the 1944 Sanitary Convention for Aerial Navigation but its use under the WHO Regulation will be optional at the discretion of individual Governments.

In future the statutory immunizations apart from those required for personal protection (i.e. TAB) will be for smallpox and yellow fever only, with cholera immunization as an occasional measure.

The author mentions and deprecates the excessive quarantine precautions taken in some of the countries of the Near East during the typhoid epidemic of 1947.

For previous communications see the series in *Bulletin* 1948, 45, 17, 1949, 46, 413. (Charles H. Cook)

WORLD HEALTH ORGANIZATION. *Manual of the International Statistical Classification of Diseases, Injuries, and Causes of Death. Sixth Revision of the International Lists of Diseases and Causes of Death Adopted 1948. Vol. 2. Bull. World Health Org.* Geneva 1948. Suppl. 1 pp. xv + 776. Review appears also in *Bulletin of Hygiene*.

The old *International List of Causes of Death* simply presented a list and did a great deal of thing under no clarity of national and international reporting. From time to time of course it has been necessary to revise the list and the World Health Organization has now issued volume 2 of the sixth revision (1948). Volume 1 will comprise the introduction and the first ten years of the list.

The introduction contains a historical review of the classification and a statement of the methods adopted by the committee appointed to make the changes in the classification of 1948 together with some 153 figures of fatal cases of injury and poisoning for characterization purposes. This occupies pages 4 to 47 and comprises three light tables. It is followed by much more extensive four-digit list based on the same figures, but extended. This occupies pages 48 to 72 and is followed by supplementary tables to show the instructions for medical certification and notes

on the rules for classification, by special tabulation lists (including lists of 150 and 50 titles), a suggested form of multiple-cause tabulation, and by the Regulations on Nomenclature adopted by the World Health Assembly

In the introduction the purpose of a statistical classification is defined, it is "to provide a list of disabilities for compiling statistics and not a nomenclature of diseases and injuries. In other words, not every condition receives a particular rubric or number, but there is a category to which every condition can be referred"

The *Manual* has evidently been prepared with great care, and in an accompanying notice issued from Somerset House there is a short indication of the procedure by which the sections were submitted to practical tests on both sides of the Atlantic, and to the detailed scrutiny of various committees

Some of the sections in the list of infective and parasitic diseases, however, should perhaps be amended when a new edition is produced. For instance, the old division of leprosy into lepromatous leprosy, neuroleprosy and mixed, has now been superseded, by international agreement, and the terms lepromatous, tuberculoid and undifferentiated have been adopted. The difference is more than a change of names. Under the heading schistosomiasis the subdivisions vesical (*S. haematobium*), intestinal (*S. mansoni*) and pulmonary (*S. japonicum*) should be discarded in view of the fact that the symptoms of *S. japonicum* infection are largely intestinal, and that the rare pulmonary manifestations can also be caused by *S. mansoni*. The filarial diseases are not differentiated except that onchocerciasis is mentioned separately, and infections with such diverse filarial worms as *Wuchereria bancrofti*, *W. malayi*, *Loa loa* and *Acanthocheilonema perstans* must all be placed together under filariasis. There are other minor points in this section which could be modified with advantage

Charles Wilcocks

WASHINGTON Proceedings of the Fourth International Congresses on Tropical Medicine and Malaria, Washington, D C, May 10-18, 1948 Vol I pp xiii+1-946 Vol II pp viii+947-1810, numerous figs & pls 1948 Washington U S Govt Printing Office

The Abstracts of these Congresses, of which the present two volumes represent the detailed Proceedings, have already been reviewed at length [this *Bulletin*, 1948, v 45, 1126]

The appearance of the full records of the Congresses indicate even more strikingly the immense range of the programme and of the papers that went to make it up and this additional review is intended to provide readers with further details of the subjects discussed and the nature of the meetings as a whole

The Proceedings are reproduced in two handsomely bound and printed volumes, each covering some 900 pages. The first 100 pages deal with such general matters as the business of the opening plenary session, the reports and resolutions eventually arrived at, the presentation of the Laveran prize to Professor H. E. SHORTT and of the Walter Reed Medal to Professor N. H. SWELLENGREBEL, a number of addresses and speeches, including the address of welcome by the Honourable George C. MARSHALL, Secretary of State, and the brilliant and penetrating after-dinner address by Dr L. W. HACKETT. This part of the Proceedings also contains a full account of the Commemoration of the Demonstration by Walter Reed of the Mosquito Transmission of Yellow Fever and the Commemoration of the Fiftieth Anniversary of the Discovery by Ronald Ross of the Method of Transmission of Malaria. Finally, the introductory chapters give a list of officers, committees, rules of procedure and the general programme

There then follow the reports of papers in the 12 sections which make up the bulk of the two volumes. The Proceedings close with the minutes of three special conferences held during the Congresses at the suggestion of representatives of the World Health Organization to discuss respectively problems of malaria, plague and schistosomiasis with an account of scientific and technical exhibits and institutions visited and with a complete list of participants in the Congresses. At the end of the second volume there is a complete index of authors of the various papers.

Some idea of the nature of the subject discussed may be obtained from the following list of sections with notes of some of the principal subjects dealt with in each. It would be impossible in a short space to list each paper or its author but each subject was dealt with by one or more well known experts whose names will be familiar to readers of this Bulletin in association with the subjects concerned.

Research and Teaching Institutes—Papers in this section referred separately to facilities in Africa, the Far East, Australia, the Americas and Europe.

Tropical Climatology and Physiology included physiological adaptation of dwellers in the tropics, deterioration and nutrition, climatology and human settlement in the tropics.

Bacterial and Spirochetal Diseases dealt with *tuberculosis* (including BCG, X-ray diagnosis and streptomycin treatment), *syphilis* and *chlamydia* (including penicillin treatment), *plague* (epidemiology, ecology, vaccination, antibiotics), *enteric diseases*, *cholera* and *electrocardiography* (the last named illustrated with some striking photomicrographs), *leptospirosis*, *tropical environment* and *fluence on infectious disease* and *leptospirosis* (with particular reference to new developments in therapy).

Viral and Rickettsial Diseases included papers on viruses in general, rickettsial diseases in particular areas, their treatment with *hydrocortisone* and the use of vaccines. Other sub-sections contained papers on *infectious hepatitis* its aetiology and epidemiology, *epidemiology and control of dengue fever*, *dengue and sandfly fever*, *poliovirus in the tropics*, the *rhinovirus*, *encephalitis* and *ber*.

Malaria constituted a long section of some 350 pages, made up of 6 sub-sections and nearly 40 separate papers. It covered all aspects of the subject giving up-to-date information on parasite-host relationships, entomology, chemotherapy with the newer drugs, immunity, control and global epidemiology.

Helminthic Diseases was concerned particularly with the physiology of helminths and their relationship to their hosts and the epidemiology and pathology of helminthic diseases. *filariasis* and *schistosomiasis* were especially dealt with and new methods of chemotherapy and control discussed.

Protozoan Diseases obtained a whole sub-section on the epidemiology, physiology, pathology and chemotherapy of *malaria* and included much information on experimental work. The second sub-section dealt principally with *leishmaniasis* and *trypanosomiasis* both African and South American.

Nutritional Diseases—the Tropics formed an important section comprising some 80 pages. It covered nutritional problems and specific deficiency diseases in several tropical areas.

Tropical Dermatology and Mycology discussed work on tropical mycoses and included papers on present knowledge of *histoplasmosis*, *coccidioidomycosis* and *South American blastomycosis*. It also dealt with *unilateral keratitis* and *dermatomycosis*.

Tropical Vectors and Parasites covered a wide range of subjects including protozoan, viral, helminthic and bacterial metazoa in the tropics.

World Health Council and other sub-sections dealing respectively with *international research*, *health administration*, *the tropics and the world health system*.

in the tropics and public health and vital statistics problems. This section contained a large amount of information on services and organization in being and proposed.

Medical and Veterinary Entomology represented a section of some 170 pages, with four sub-sections. The first dealt with *mosquitoes and disease*, the second with *flies*, the third with *ticks, mites, lice and fleas* and the fourth with *triatomata, insecticides, toxicology and equipment*. This important section covered various regional aspects of entomological control and epidemiology and a great deal of information on the nature, toxicology and use of insecticides.

The volumes contain a number of excellent photographs and other illustrations.

These notes give a very brief account of a monumental piece of work. The wide range of subjects covered, the vast amount of up-to-date information contained and the distinction of those contributing to the Congresses are not only evidence of the success of the Congresses themselves, their record in two large volumes has resulted in what is in fact a large compendium on recent advances in tropical medicine and hygiene, to which all workers in tropical diseases can turn for reference with advantage and profit.

H J O'D Burke-Gaffney

AFRIQUE OCCIDENTALE FRANÇAISE. Rapport sur le fonctionnement technique de l'Institut Pasteur de l'Afrique Occidentale Française en 1947 [DURIEU, C.] [Technical Report of the Pasteur Institute in French West Africa in 1947] 128 pp 1949 Dakar Grande Imprimerie Africaine

This Report is on the lines of its predecessors [this *Bulletin*, 1949, v 46, 416]. The following points of special interest are noted.

The total number of specimens examined increased to 37,354 of which 18,162 were bacteriological, cytological and parasitological, 14,943 were serological, 3,782 chemical and 425 histopathological [the last-named are incorrectly shown as 14,943, the figure for serological examinations]. The Institute issued 19,368 ampoules of 6 cc each of rabies vaccine during the year. There were 49 anti-rabic treatments at the Institute and 473 at the other centres, with no deaths or paralytic accidents. It is added, however, that six deaths from rabies were reported which occurred in 1946—one each from French Sudan, Dahomey and Senegal and three from Togoland. Detailed statistics are given of the anti-rabies service and brief accounts of the cases referred to above.

A lengthy report is given of a transient paralytic condition which occurred in a European, and which lasted about a fortnight, after inoculation with a vaccine from Yaba, Nigeria. Bacteriological tests and animal inoculations from this vaccine failed to show any evidence of any neurotropic virus or other pathogen.

Vaccines and other biological products prepared at the Institute in 1947 amounted to over eight million doses or cc.

Vaccination against yellow fever was carried out in 3,109,638 cases. Yellow fever occurred only in Sudan—there was a small focus at Bamako which accounted for three European deaths. Prompt measures rapidly eliminated this focus.

Mention is made of a follow-up investigation carried out at the Swiss Tropical Institute at Basle on 476 persons who had received the Dakar Institute yellow fever vaccine. A short-lived reaction with mild pyrexia was found in 120 (25.2 per cent), a more severe reaction in 32 (6.7 per cent) and no appreciable reaction in 324. Later tests in Dakar showed that these persons had developed a solid immunity. Serum protection tests were carried out on 260 human and 47 animal sera. In two cases the tests were made for diagnostic purposes. Both patients showed, clinically, features suggestive of yellow fever, although

both had received yellow fever vaccine and both died. One patient (a European) who had been vaccinated previously at Marseilles gave a negative test but yellow fever virus was isolated and at autopsy typical liver lesions were present. The other (an African) gave a strongly positive protection test on the third day and autopsy showed that the condition was infectious hepatitis.

Lengthy details are given of protection tests carried out to control yellow fever infection. An epidemiological enquiry was made in two towns on the Coast of French Somaliland, where protection tests were carried out on 100 Africans—only two were positive & both in Africans, one of whom had been certainly and the other probably vaccinated against yellow fever.

Among the 47 animals tested (all but one being baboons, *Papio papio*) there were five positive serum protection tests—all in animals from Guinea.

Among the special investigations referred to in the report is a lengthy discussion on the therapeutic properties of cinchona—this subject has been discussed at length in this Bulletin (see above).

There are also discussions on tick-borne relapsing fever in Senegal and the rat as a reservoir. Of 51st rodents and insect-bites examined at Dakar 85 (19.55 per cent) were infected with *S. duttoni* especially *Cricetomys gambianus* and *R. rattus merriami*—the local vector is *Ornithodoros erraticus*.

A number of records are given of vitamin A estimation in Africans in Dakar and of vitamin C in the fruit *Detar* (*Detarium senegalense*) which contains about 2 per cent of the vitamin—some of these have already been referred to in this Bulletin (1919 v 46 1931).

An interesting study is reported on the chemical composition and caloric value of termites which are eaten extensively by certain African tribes. It is shown in tables that living termites contained 24.25 per cent fat, 23.22 per cent protein and a caloric value 1,747 per 100 gm. corresponding figures on cooked (fried) termites were 33.15, 45.62 and 5021. Corresponding calories for beef and dried salted fish (quoted from TIMON) and ground nut (MULLAND) are given as 1,77, 203 and 584 calories.

The Report ends with an account of the experimental situation at M'Elmor and three pages of listed publications by members of the staff of the Institut.

H. J. O'D. B. Le Gallier

BULL. INST. HYG. MAROC, 1947 v 7 125-32. Rapport sur l'activité de l'Institut d'Hygiène pendant l'année 1947. Annual Report of the Hygiene Institute, Morocco for 1947.

In the Institute 28,347 microbiological and other medical laboratory examinations were made in 1947. In addition to these 458 histopathological and over 1,000 chemical examinations were undertaken.

Epidemiological services included a scheme for vaccination of the population against smallpox every four years studies of the measures to prevent the introduction of cholera into Morocco and investigations on schistosomiasis.

Six anthelmintic missions were an operation in the country during the year and were concerned with ascarid infested breeding places, control mass treatment and general epidemiology.

It is recorded that *proteus* was determined in the case of 3 febrile nephropathy cases and 718 adults. The predominant species of malaria was *A. maculiparvus* (presumably *A. schicki*) (79 per cent) of which *A. turkestanicus* accounted for 28 per cent, *A. latrans* 1 per cent and *A. setaceus* 10 per cent. Other species were *A. malayensis*, *A. mearnsi* and *A. concolor*.

Parasites were found in 2,008 (19.07) blood films of 12,438 persons 53 per cent *P. falciparum* 34 per cent *A. mearnsi* 13 per cent.

Studies have shown that *A. turkestanicus* which spread, but its vector is not clearly established. The same view is expressed regarding *A. setaceus*.

[see also this *Bulletin*, 1949, v 46, 317] It is stated that *A. claviger* is a notable vector at high altitudes, but is stated to be without danger below an altitude of 1,000 metres, because its development ceases before the temperature allows sporocysts to develop [See also this *Bulletin*, 1949, v 46, 432]

A brief note is given on air-spraying with larvicides and on the treatment of malaria with the newer synthetic products. It is noted that doses of proguanil [paludrine] between 0.3 to 1 gm daily resulted in disappearance of *P. malariae* from the peripheral blood only in 6.5 to 11.5 days (average 9), in 12 cases while in 28 cases of *P. falciparum* and 20 of *P. vivax* infections, the same dose produced disappearance of the parasites in 2.4 and 3.9 days respectively.

Biochemical studies included investigations on cholinesterase and the refractive index of serum. It is stated that both are lowered almost constantly in malaria and that quinine, quinacrine [mepacrine], nivaquine, and paludrine [proguanil] all have a definite anti-cholinesterase activity [but no details are given].

The anti-tuberculosis service was interrupted for several months, but tuberculin tests and radiographic examinations were made on 12,583 persons in urban areas (Fez) and rural areas (Merchouch and Skoura du Guigon). A summary of the results is shown in a short table.

H. J. O'D. Burke-Gaffney

BULL. INST. HYG. MAROC 1947, v 7, 133-94. Rapport sur l'activité des Services de la Direction de la Santé Publique et de la Famille pendant l'année 1947 [Report on the Activity of the Public Health and Social Welfare Services during 1947].

Public health conditions in Morocco in 1947 were much more satisfactory than during the previous two years. The disasters of 1945, drought, famine, malnutrition and an epidemic of relapsing fever, were still affecting health conditions in the early months of 1946. Relapsing fever was declining, however, and had practically disappeared in August 1946. In 1947 typhus fever had also a much lesser incidence, only 126 cases were reported. Deaths in 1947 numbered half those in 1946 and only a third of the 1945 figure.

Consultations in hospitals and dispensaries in 1947 numbered 9,654,876, wounds 38.5 per cent, fevers 42, and venereal diseases 19 per cent. Admissions to hospital numbered 89,000.

Vital statistics are available only for the 18 municipal towns. Data for Europeans are exact, for the Jewish population approximately correct, for the Musulman population unreliable. The Musulman population of these towns is largely a floating one. The death rates per 1,000 in 1947 were Europeans 8.5, Jews 15, Musulmans 15, as compared with 10, 19.8 and 36 in the very unhealthy year 1945. More than half of the Jewish deaths and a third of the Musulman deaths were those of children under two years of age.

Trachoma is very prevalent, new cases treated in 1947 numbered 87,232. Only 61 cases of smallpox were notified against 1,870 in 1946. Measles is an important cause of infant mortality. There were 68 cases of scarlet fever notified but none fatal. Diphtheria notifications numbered 334, the fatality rate was low. Seven cases of anterior poliomyelitis and 29 cases of cerebrospinal meningitis were notified. Tuberculosis is widespread. There were 183 new cases of leprosy of which 64 were in the Fes-Taza region. Typhoid-paratyphoid infections were less in evidence, 902 cases as compared with 1,579 in the previous year. These diseases are essentially urban, affecting chiefly the European and Jewish elements of the populations.

There were only 19 sporadic cases of relapsing fever, tick-borne. The 126 cases of exanthematic typhus were the lowest number ever recorded. The increasing use of DDT probably contributed to this decrease, 216,000 anti-typhus

vaccinations were performed. The last case of plague occurred in October 1915. 124837 rats were captured. There was no cholera—the outbreak in Egypt necessitated special precautions.

The report gives detail of new hospitals under construction including a tuberculous sanatorium of 280 beds, in the hills and a tuberculosis pavilion of 100 beds at a hospital at Casablanca. November 1944

Cook, C. F. *The Native in relation to the Public Health.* *M. J. J. Austral* 1919 Apr 30 v. 1 No 18 569-71

The author, than whom there is probably none more experienced in the problems of their relationship to Europeans and Western civilization traces the changes in the life of the Australian aborigines in the less settled part of western and northern Australia, from their unclothed food-gathering nomadic existence when the continent was discovered to the present position, which is further complicated by an increasing half-caste population. In their original condition the scarcity of food necessitated their constant wandering over wide areas in small groups. This effectively prevented the development of epidemic infections and at the same time excluded them from developing any empirical preventive medicine. European occupation in the areas concerned is still very sparse but has from the start always encouraged the settling of the aborigines round homesteads and townships to reduce disturbance and killing of their stock and to have labour readily available. This new mode of life offered a virgin field for infections and epidemics and is usually associated with unsanitary conditions and squatter.

In the inevitable and present close contact of aborigines, half-castes and Europeans the author recognizes a grave health problem, particularly as regards leprosy, ankylosing spondylitis, amebiasis, malaria and tuberculosis.

Clearly the adaptation of the native to community life and his successful integration into the white social structure are public health problems of the first importance. "No government department is more stultified and more suitably equipped for attempting the solution of the problems arising from this failure to orientate the native component into the nation's general population than that of public health."

The author then deals with the necessary measures. These include broad education of both sections of the population, adequate housing of aborigines and half-castes, and special but fundamental requirements for the northern areas. He admits that the cost would not be light and in the absence of popular demand its financing from State or Federal budget will be difficult.

Should public health requirements not weaken popular opinion the author points out that uneducated bewildered, without a place in the social structure—the native hybrid must remain a ready prey to agitators and a fertile field for subversive ideologies. That this section is rapidly increasing in numbers and may soon dominate the population in isolated areas. It is a further emphasis from the point of view of national defense. (Continued from 1942.) C. J. Hackett

BOOK REVIEWS

DÉVÉ, Félix. *L'échinococcose osseuse* [Hydatid Disease of the Bones]
236 pp, 30 figs 1948 Paris Masson et Cie, 120 Boulevard Saint-Germain
[700 fr]

— *L'échinococcose primitive* (Maladie hydatique) [Hydatid Disease]
362 pp, 63 figs 1949 Paris Masson et Cie, 120 Boulevard Saint-Germain [1,000 fr]

The first of these two remarkable memoirs, both of which are in the French language, is devoted to osseous hydatid disease. It is edited by the doctors of Uruguay in homage to its author and is dedicated by the author to Professor Domingo Prat, of Montevideo, Professor Oscar Ivanissevich, of Buenos Aires, and to Daniel J. Cranwell. It is a treatise which can hardly be neglected by anyone interested in its subject. With characteristic modesty, Professor Dévé says that, if he has throughout the work, given his own views, this is not because he wishes to impose them upon others, but because he wishes to call attention to problems as yet unsolved and to provoke discussion and criticism. Certainly no reader could accuse him of seeking to impose his own views unfairly, for, throughout the work, he quotes the work and views of others, giving abundant references to the literature, and his pages are full of reasons why he does not agree with some other writers. He believes, for instance, and gives his reasons for believing, that osseous hydatids are not different from alveolar hydatids, but take the forms, which he so well describes, because the parasite, when it enters the rigid "Procrustean bed" of bony tissue, suffers a structural alteration and a biological change, which determine its peculiar forms and can be compared, as LEUCKART compared it, to the racemose form sometimes assumed by *Cysticercus cellulosae*. Intermediary forms between osseous and alveolar hydatids do exist, in spite of the denial of their existence by POSSELT. Dévé concludes also that Virchow's original conception that multilocular hydatid of the liver is only a particular form of hydatid cyst can be maintained, but only in the sense that these two modes of structure and development are forms assumed by the same parasite. There is, that is to say, only one species of *Echinococcus*. Its alveolar form is a secondary derivation which becomes specific and definitive and its osseous forms are determined by the rigidity of the bony tissues around it. His reasons for this view are expressed throughout this memoir and can only be appreciated by careful study of the whole book.

It is, indeed, impossible to do justice to this memoir in a brief review. Its range and detail are too considerable for that. In the introduction the author points out that osseous hydatid disease constitutes only 1 per cent of all cases of hydatid disease, so that it is rare. It is, however, clinically interesting because it is symptomatically silent for a long time so that the lesions caused by it extend considerably before they can be discovered, and it is pathologically interesting because of the indefinite progression of the lesions in the bone affected and their frequent propagation to neighbouring bones. It also often develops in positions which prevent its surgical removal.

Pointing out that the initial phase of the osseous hydatid has never been seen in man and cannot be studied in him because it never declares itself until it is in an advanced phase or complications have developed, Dévé describes in detail his experimental introduction of hydatid sand into rabbits and other animals and the osseous disease that resulted, comparing his results with those obtained by others. He concludes that bone is a relatively favourable medium for the development of hydatids and that bone has little power to resist their development, a view also held by GANGOLPHE. Bone tissue, says Dévé,

seems to confer on bvd taks a particular vitality a relatively mal nant character. The pathogenic process includes (a) A mechanical process namely a series of disorders caused by the simple expansion in the bone of the hyalid cyst full of fluid under tension and the erosion of bone by pressure upon it and its atrophy. The cyst moulds itself to the bone irregularities, ramifying and taking an irregular form partly owing to the formation of irregular diverticula from the original cyst formed because the resistant bone prevents the normal expansion of a spheroidal cyst. These diverticula may be bifurcated or angular and coalescence of the internal germinal layer lining them may cut off some diverticula from the original vesicle so that independent cysts are formed. In addition to this there is exogenous proliferation which also gives rise to new vesicles. These reproduce and propagate the pathogenic process so that multilocular cysts arise. A series of independent vesicles thus arises in the bone cavities which continue the process by more exogenous budding, so that a sort of colony of the cysts is formed.

(6) **Necrosis of bone** Relatively unimportant forms of this are superficial toxic necrosis and the formation of small sequestra. The most important form of it in man is the massive necrosis due to ischaemia which is seen in advanced stages of erosion.

(c) **Abscess formation**—which is the chief process which destroys both pulp and compact bone. It is not accompanied by inflammation and no fibrous tissue is formed round the isolated prosthesis, provided that infection does not occur.

While the author's views on the development of the parasite and on the manner in which it produces its effects are particularly interesting and valuable, the rest of the book will be for some readers even more interesting. There is not space to consider here all that the author has to say on the aetiology, symptoms, diagnosis, complications, prognosis and treatment of this disease. For the author's summary and discussion of these aspects of ovarian hydatid disease the memoir itself must be consulted. It is likely that it will be consulted by many readers in the years to come for here we have the words of a man whose lifetime of experience and everyone who has ever met such hydatid disease in any form will be grateful for it.

The second memoir listed above is a worthy companion of the first. Some what longer, it amounts to a detailed discussion of the biology and life of hydatid cysts, the treatment of them and the aetiology of hydatid disease. Its geographical distribution and its prophylaxis. Some medical men will no doubt find this volume more useful than the one just reviewed.

The memoir is divided into two parts. Part I, I, with the tracter biology and medical a pect of *Fek* covers Part II with it greater pt al l t that an and with the aetiology and prophylaxis of hydatid disease. A useful list of the first part is a list of the popular names given to it by local live w countries. Then follow description of the adult specimens and the first in the dog a list of its other host and of the host of the hydatid stage and a valuable detailed description of the hydatid cyst itself and of its development and certain anomalous forms of it. The author could have gone on at length to discuss here that there is only one species of *Fek* and to discuss the pathological anatomy and pathogenesis and etiological and pathological relations of hydatid disease with the various organs of the liver to tubercles, tuberculosis and cancer and to make a list of the symptoms and evolution of the disease and to apply it to the various cases considered and then the diagnosis, prognosis and treatment.

The section on art, which opens Part II of the memoir, is one of the parts played by dogs and cats, the cat being operated from 11 drawings. The part played by age, sex, family relation and the manner in which the dog was shot, the considerable sections on the geographical distribution of both the dog and

and on its prophylaxis will be the most useful in the book for these are not dealt with in textbooks in the detail given here. No less valuable are the references to the literature. Certainly every parasitologist will find this memoir invaluable. If he has also the memoir briefly reviewed above and the same author's "*l'Echinococcose secondaire*" (Paris: Masson et Cie et Paul Deval, 1946, 241 pp., 59 figures), he will have, recorded by a master, a detailed discussion of every aspect of this remarkable parasite and its effects. G Lapage

KLEINE, Friedrich Karl. *Ein deutscher Tropenarzt* [A German Tropical Doctor]. Einführung von Herbert KUNERT. 182 pp., 19 figs. 1949. Hanover: Schmorl & von Seefeld Nachf. [D M 12]

All who have had the honour and pleasure of working with Professor Kleine or of being otherwise associated with him in tropical Africa will welcome the appearance of this book, and it will also have a special interest for those whose duties bring them into contact with human and animal trypanosomiasis. It has been published as a tribute to this distinguished research worker in tropical medicine on the occasion of his reaching his 80th birthday.

Kleine's studies of tropical diseases of man and animals during nearly fifty years began when he accompanied Robert Koch in 1903 to Rhodesia to investigate what proved to be African Coast Fever in cattle. A few years later he again accompanied Koch as a member of the German Sleeping Sickness Expedition to German East Africa, and he afterwards devoted most of his life to the study of this disease. In 1909 he proved by simple experiments that trypanosomes develop in tsetse flies for a few weeks before the flies become infective [as Koch suspected in 1905 from his observations on the "proboscis drop"], transmission by tsetse flies was therefore chiefly indirect and not merely mechanical as other workers had thought. Kleine's work on sleeping sickness was interrupted by the first World War in 1914, but in 1922 he went to Rhodesia and the Belgian Congo to test the new drug "Bayer 205" (Germanin) in human and animal trypanosomiasis, in 1926-7, as a member of the League of Nations Sleeping Sickness Commission, he carried out researches in Uganda, Kenya and Tanganyika Territory. He has since spent much of his time in East and South Africa.

The book consists mainly of reprints of interesting accounts which Kleine wrote from time to time of his various visits to Africa, this is preceded by a short preface and a biographical introduction by Professor Herbert Kunert. At the end of the book are a chronological index of Kleine's published papers and an index of names of people mentioned in the book. There are 19 photographic illustrations on 12 plates, they include portraits of Kleine, Koch and David Bruce, some East African scenes, and two poor photographs of *Glossina morsitans* and *G. palpalis* whose labels seem to have got transposed.

As in the case of Robert Koch, a biography of Kleine is largely a record of his research work, but personal qualities such as his perseverance in difficulties, his sense of humour and his unvarying courtesy, so well known to his friends and co-workers, are revealed in these accounts of his travels. The reviewer remembers his reply to doubts expressed whether a lorry could get through the swamps and floods to Ikoma, a 90-mile journey, it was "It is astonishing what a motorcar can do." During the last thirty years Kleine has been accompanied on his travels by his wife, whose cheerful endurance of primitive "bush" conditions, including rat-infested houses, was much admired, and whose many kindnesses to people who, like the reviewer, shared some of those conditions, are gratefully remembered.

KIRK, J. Balfour (C.M.G. M.B. Ch.B., F.R.C.I. D.I.H. D.T.M. & H. etc.)
A Manual of Practical Tropical Sanitation. 2nd Edition. pp. vii + 286
 46 figs. 1949 London: Baillière Tindall & Cox, 7 & 8 Henrietta Street
 W.C.2. 10s. 6d.

The first edition (see this *Bulletin* 1937 & 74 1937) of this manual was a most useful book, designed for sanitary inspectors and for managers of plantations and mines who should know the fundamental facts of the causes, transmission and prevention of disease in the tropics. There are not many books of this kind. This second edition can be recommended very confidently. It is largely a reprint of the first edition with additions to bring it up to date, but as the general principles of the subject have not changed much since 1937 the older material retains its value. The author's style is clear and interesting, and the format is attractive though the print is slightly smaller than in the original edition. However it is still quite big enough to be read with comfort. The illustrations are the same as before (including the intriguing picture on p. 253 of the aqua privy where the user must sit astride, perch himself (or herself) on the end of a 6-inch drain-pipe and hope for the best).

Many additions have been made but they have been kept so brief that the book has not been greatly lengthened and there are some deletions. For instance DDT and benzene hexachloride are described, and their uses are detailed—a section has been added on poliomyelitis (but there is no reference to this in the index). ANTU is included (p. 135) among the rat poisons (but the proof reader has allowed *Rattus Norvegicus* to elude him). Some of the new anti-malarial drugs (but not chloroquine) are mentioned, though the measures suggested for suppression are smaller than those now accepted.

On the other hand, there are some important omissions. The spread of *Entamoeba histolytica* by water is not mentioned. There is no reference to jungle yellow fever, the process of transmission in malaria is not described, though immunity in other diseases is discussed. Scrub typhus and murine typhus are not described. These however are small defects in a book which will be of the greatest value to sanitary inspectors. It contains chapters on elementary anatomy and physiology, the communicable diseases, entomology, disinfection, housing, food, milk, water, sewage, refuse, London's schools and village sanitation. The author writes with the authority of his long tropical service as a health officer and as a Director of Medical Services.

MALARIA

SAUTET, J. Etat actuel du paludisme et de l'anophélisme dans la région méditerranéenne [Present State of Malaria and Anophelism in the Mediterranean Region of France] *Rec Travaux Inst Nat Hyg Paris* 1944, Tome 1, v 2, 176-96, 4 figs

This is a record of the results of investigations carried out in the Mediterranean regions of France during 1943. At that time there were in that area a large number of immigrants from non-malarious areas, who were under continuous observation.

The history of malaria in southern France prompted special attention to three districts, Perpignan, the southern part of the Gard Department, and the Little Camargue. In the Perpignan region malaria was very prevalent from 1939 to 1942, as the result of the arrival of numerous infected refugees from Spain. Canet was the centre of this outbreak which extended westward to Perpignan, southward to Argeles and northward to the Salces Swamps. In 1942 there were 126 cases in Canet alone. By 1943 the outbreak was all but over, only a few cases were found in Canet village. The suppression of the outbreak could not be ascribed to measures of control which were limited to the treatment of the sick.

In the south of the Gard Department, 28 cases of *P. vivax* malaria were reported in 1942 among 3,000 young people who had come to help in the grape harvest. Most of these patients had presumably acquired their infections before arrival. There was no evidence of malaria in this area in 1943.

The most malarious region in 1943 was the Little Camargue. Forty-two primary indigenous cases of malaria were observed in or around Saintes-Maries de la Mer, in September and October. In the latter month, 69 cases of *P. vivax* malaria were also observed among immigrants. *P. vivax* was the only species found. Clinically the disease was mild everywhere.

Elsewhere in southern France there was little or no evidence of locally acquired malaria in 1943.

In the Perpignan area four races of *A. maculipennis* were found, *typicus*, *messeae*, *atoparous* and *cambournaci*. The same races were found in the south of the Gard Department where some specimens of *melanoon* were also found. Adults were plentiful in stables and cattle sheds but rarely if ever found in human dwellings. In Camargue *A. hyrcanus* is reported in addition to the five races of *A. maculipennis* mentioned above. Here zoophilism is somewhat less marked than in other areas, *A. maculipennis* was often found in dwellings though in less numbers than in cattle sheds, etc. Nowhere were anophelines found breeding in salt water.

Anopheline breeding places are restricted to irrigation canals and small collections of water. Larvae were seldom if ever found in large swamps and marshes. Large reclamation works are not called for.

[The impression conveyed by this report is that the probability of malaria becoming a serious menace to the health of southern France is exceedingly remote in spite of the very defective sanitary conditions in which sections of the population are living.]

Norman White

ROBERTS J. I. The Parasite Rate in High Altitude Malaria. *J Trop Med & Hyg* 1949 Aug 52, No. 8 160-69

This paper is largely an analysis of the results of the examination of thick drops of blood taken from hospital patients in Nairobi, Kenya, during the years 1933 to 1944. The blood was stained by Field's method, and *Plasmodium falciparum* was the only species considered. The figures indicate that an epidemic took place in 1940 when the incidence of positive slides was 23 per cent, as compared with 9 per cent. in the previous two years gradually reverting to 9 per cent. by 1944. All races (European, Asian and African) participated in this epidemic though the increase was most marked amongst the Asians. Malaria rates ordinarily become higher throughout the months of January, February, and March, i.e. at a time prior to heavy rainfall and a greater density of the vector, then for about 10 to 14 days before the onset of the rain there is said to be a very decided increase in these rates. It is suggested that this phenomenon is due to some change in the virulence and tenacity of the parasite itself. *Anopheles gambiae* was the vector and although the population had a high crevcent rate the sporozoite rate was unaccountably very low.

The author states that at the high altitude (5,400-5,700 feet) malaria assumes a lowly and mild form often unaccompanied by fever with scanty parasites in the blood and little anaemia. Frequently these nearly symptomless cases, if untreated progress to an intractable state of chronic debility.

[The title of this paper is misleading. Its contents do not deal with the parasite rate but with the incidence of *P. falciparum* in blood slides taken from hospital patients while the high altitude malaria affects only a single town at an altitude much lower than that of many epidemic localities.]

P. C. C. Garabam

LACIDAJER J. Species and Races of Malaria Mosquitoes occurring on the Coast of the Gulf of Gdansk. *Bull. Inst. Mar. & Trop. Med. et Mal. Gdansk, Poland* 1949 v. 7, No. 1-2 91-4 1 map.

The biology and distribution of anophelines on the southern and western coast of the Gulf of Gdansk (Danzig) were studied in 1947-48.

The delta of the Vistula, the western coast of the Gulf of Danzig and the Hel Peninsula together constitute low-lying terrain much of which contains collections of water such as bogs, landlocked bays, streams and ditches. These and artificial water holes are fed by war operations provide conditions very favourable to the development of mosquito larva.

The mosquito races were determined from eggs collected in these places or laid in the laboratory. The adult female mosquitoes were caught in their daytime resting places or in their winter quarters, e.g. stables, cellars and human dwellings.

The anophelines found were *Anopheles claviger* and the three races of *A. maculipennis*. The re surveyed is shown a map divided into four sections. *A. maculipennis maculipennis* was the least commonly found on the coast and

Malaria

Vol 46, No 12]

was not detected at all on the Hela Peninsula. *A m messeae* flourished in the fresh-water regions, while *A m atroparvus* was most prominent where the water was mixed with salt from contact with the sea, e.g. mouths of rivers and land-locked bays. The percentage findings of each type in the four sectors are shown in a table which shows the great preponderance of *messeae*, except in the Hela Peninsula. Another table indicates the mean numbers of eggs laid at one time by female *messeae*, *atroparvus* and *maculipennis*, which were 162.4, 140.8, 133.5 respectively.

The author points out that between races of *A maculipennis*, especially *messeae*, in different countries there is some difference in the structure of the egg, owing to variation in the number of float ridges. The figures given are for Sweden (14 to 21), Holland (18 to 32) and the Polish Coast (18 to 28).

It is evident that anophelines are present in the whole coastal belt of the Gulf of Danzig. On the respective capacities of the different races to act as local vectors of malaria will depend whether the disease will acquire endemic characteristics, and this has yet to be determined. *A m atroparvus* is a vigorous feeder and viable even in winter and is very frequent on the Coast. *A m messeae*, though less liable to be infected, may be of epidemiological importance because of the large numbers present, while *A m maculipennis* is markedly zoophilous and occurs in comparatively small numbers in the area described.

TERREIRA T S da C, PINTO, A R & DE ALMEIDA, C L. Alguns dados sobre a biologia do *Anopheles gambiae* da cidade de Bissau e arredores (Guiné Portuguesa), em relação com a transmissão da malária e filariase linfática [Facts on the Biology of *Anopheles gambiae* in the City of Bissau and its Neighbourhood, Portuguese Guinea, and its relation to the Transmission of Malaria and Filariasis]. *An Inst Med Trop* Lisbon 1948, Dec., v 5 223-50. 5 text figs (1 map) & 16 figs on 8 pls [14 refs] English summary.

The paper reports a large amount of work carried out in Bissau and its neighbourhood in Portuguese Guinea. The situation is evidently the same as what is familiar in West Africa.

Among the domestic mosquitoes *A gambiae* is much the most numerous species. The average anopheline rate per house being about 11 with a maximum of 14 to 25 per cent in the dry and wet seasons respectively. Larval nematodes which the authors identify as *Il bancrofti* were found in the proboscis in 0.51 per cent of the dissections. [The identification may be correct, but it would be well to accumulate convincing evidence on that point.] Precipitin tests carried out on *A gambiae* were positive with anti-human serum in 55 per cent. The children's spleen rate was 57 per cent and parasite index 58 per cent. Most of the malaria parasites were *P falciparum*.

HORSFALL W R & PORTER, D A. Biologies of Two Malaria Mosquitoes in New Guinea. *Ann Entom Soc Amer* 1947, v 39 No 4 549-60. 4 figs 11 refs. [Summary taken from *Rev Applied Entom* Ser B 1949 July, v 37 Pt 7 128-9].

Anopheles punctulatus Dön., and 4 *farauti* Lax. are the principal vectors of malaria in New Guinea and adjacent islands and possible vectors of filariasis (caused by *Filaria (Wuchereria) bancrofti*) in parts of these areas. An account is given of observations on their bionomics made during 1943 and

1944 in eastern and northern Papua and on Bial in the Schouten Group. *A. punctulatus* was most abundant on heavy clay soil, whether at sea level or inland, and was reported to occur as high as 3,500 ft. in the mountains. *A. farauti* was present on the coastal plains where the soil was sand or mud, and both species occurred where the soils intergraded. Larvae of both developed largely in sunlit ground pools, *A. punctulatus* mainly in depressions such as tracks of all sorts, especially in clearings incident to construction of army camps and *A. farauti* in natural pools, particularly those with floating sticks or vegetation and grassy margins of sluggish streams. *A. farauti* also bred in partly shaded sections of mangrove swamps subject to only slight tidal fluctuation particularly if floatage was abundant.

A. punctulatus required on the average one day less than *A. farauti* for the egg stage and each larval instar. The mean durations in days of the egg, larval and pupal stages in the laboratory were 2.5, 7.5 and 1 for *A. punctulatus* and 3.5, 11.3 and 1.2 for *A. farauti*. In the field, under very favourable conditions in sunlit sites, the former may complete larval and pupal periods in five or six days. Applications of larvicides must therefore be repeated every five days to ensure its control but once a week was adequate where only *A. farauti* was present.

Eggs of both species may be deposited on moist surfaces or on water. Those on moist surfaces incubated at the normal rate but did not hatch until flooded; they remain viable for 14 days. Larvae of *A. punctulatus* were very active but those of *A. farauti* moved little except when disturbed. Adults of both species were collected on moist banks near villages. *A. punctulatus* was most commonly taken on vertical banks out of direct sunlight within a few feet of a frequently used trail or place where natives sat on the ground to work. The limit of effective flight-range of *A. punctulatus* was determined, by elimination of larvae by oiling in a native area near Oro Bay to be $\frac{1}{2}$ mile. Females at a collecting site at this distance from the untreated area were reduced by about 97 per cent. The population returned to normal within six weeks.

Dissection of 414 females of *A. punctulatus* that had probably fed only once in the wild in an area where malaria was prevalent showed oöcyts in 50 and sporozoites in three. Of 132 females of *A. farauti* examined, five contained oöcyts and none sporozoites. Unidentified filarial larvae presumed to be *Filaria (H. uckeri)* sp. were found in 3.8 per cent. of *A. punctulatus* and 3 per cent. of *A. farauti*.

LEVI CASTELLO Roberto. Atlas de los anelasma Sudamericanos.

This book is reviewed on p. 1193.

LOCKERT G. Quadried atteggiamenti midollari della malaria cronica. [Reaction of Bone-Marrow to Chronic Malaria Infection.] *Riv. di Malaria* 1948, Dec., v. 27 No. 6, 231-53. [29 refs. English summary (9 lines)]

For a long time the author has been engaged in a study by means of sternal puncture of changes in the bone-marrow that occur during chronic malaria infections. In this paper he gives the result of differential cell counts of the marrow in seven patients suffering from chronic malaria. The reaction of the marrow to the infection is essentially parenchymal and haematogenous (sic). The changes are varied and inconstant. There is rarely any marked change in the reticulo-endothelium. The author believes that the destruction of red cells is not solely responsible for the changes in marrow structure observed; asthenic, inhibitory and toxic factors are also involved. Vernia White

REIN, C R, BUKANTZ, S C, KENT, J F, COOPER, W C, RUHE, D S & COATNEY, G R Studies in Human Malaria. XIX The Course of the Complement-Fixation Reaction in Sporozoite-induced St Elizabeth Strain Vivax Malaria *Amer J Hyg* 1949, May, v 49, No 3, 374-84, 2 figs [15 refs]

The course of the complement-fixation test was studied for 18 months in 87 prisoner volunteers infected with sporozoites of *P vivax*, St Elizabeth strain. The antigen used was an alkaline phosphate buffer extract of *Plasmodium knowlesi*. A total of 6,604 samples of serum were examined during the course of the study. Positive serological reactions were associated with all but 4 of 199 malaria attacks affecting the 87 subjects.

Positive complement-fixation reactions appeared in primary attacks 7.2 days after patent parasitaemia and 6.2 days after the onset of fever (averages). In relapses these intervals were 4.4 and 2.3 days. The test remained positive for 42 days during primary attacks and for 125 days during repeated relapses.

The complement-fixation test might be useful in identifying recently subsided attacks of *P vivax* malaria but would be of no value in diagnosis early in an attack or in the long latent period between early and late activity. During recurrent attacks the test could detect more infected persons than could the examination of blood smears.

Norman White

FIELD, J W Blood Examination and Prognosis in Acute Falciparum Malaria *Trans Roy Soc Trop Med & Hyg* 1949, July, v 43, No 1, 33-48, 12 figs [14 refs]

Divergent opinions as to the frequency or rarity of severe cases of untreated falciparum malaria with "negative blood slides" and as to the value of blood parasite counts in the prognosis of falciparum malaria prompted the observations recorded in this paper. Records of 2,136 cases of acute uncomplicated falciparum malaria that were treated in the Government Hospital adjoining the Institute for Medical Research, Malaya, during a number of years, were studied. Fifty of the patients died. Parasites in blood films were counted daily during treatment. Thirty-nine of the deaths were in patients whose peripheral blood before treatment showed at least 100,000 parasites per cmm. Only three fatal cases had peripheral blood parasite counts of less than 10,000 per cmm. It seems clear that in Malaya parasite counts in adult Asiatic patients suffering from untreated falciparum malaria are of great prognostic significance, high counts indicated a high risk, low counts a low one.

When parasitaemia is reduced by treatment, prognosis from blood films becomes less reliable. Death may occur when the number of parasites has fallen below the level at which they may be found by thick-film examination. Most of the fatal cases in this series, however, still showed high parasitaemia on the day of death.

Schizonts are more likely to be associated with high levels of parasitaemia, their presence at lower levels of parasitaemia did not necessarily indicate clinical gravity.

The author is sceptical of the view that serious, even fatal, falciparum malaria may occur without parasites ever reaching the peripheral blood. Valid evidence of such occurrence must meet the demands that other possible causes of the symptoms are excluded, the parasites have not receded from the blood as the result of earlier treatment, the staining is reliable, parasites are found at autopsy in vital organs.

Six patients in the series survived infections with parasitaemia of 500,000 per cmm or more.

The author advocates the adoption of routine parasite count in all serious cases of *falciparum* malaria. Made before treatment is commenced they give information which cannot be obtained in any other way. The technique is simple—a count of parasites per 1 000 red cells in a Romanowsky-stained thin film and a total red cell count.

Norma Blake

MORALLS A. B. ORTIZ, A. L. & GARCIA, L. S. Malaria simulating Acute Appendicitis. *J. Philippine Med. Ass.* 1949 Mar., v 25 No 3 135-40.

After removing normal appendices from two patients with symptoms of acute appendicitis who later responded to antimalarial therapy, the authors adopted a more critical attitude towards patients with a diagnosis of appendicitis in malarious countries. They report six cases in which a diagnosis of acute appendicitis was either considered or made but in which further investigation revealed a malaria infection as the cause of the symptoms.

In all six patients the localizing symptoms—pain and tenderness in the right iliac region—occurred after several days of malarial fever and sometimes vomiting. This fact and the finding of a normal or low leucocyt count led the authors to suspect malaria which was confirmed by the finding of malaria parasites in the peripheral blood in each case. The infecting parasite was *Plasmodium falciparum* in five cases and *P. vivax* in one.

The authors consider that the cause of the symptoms is the blocking of the capillaries of the mucosa and villi and they discuss the course of the nerve impulses set up locally in the appendix and caecum by this protozoal infection.

L. E. Napier

COLTZEN A. Malaria congenita. Congenital Malaria. *Rev. d. Mal. d. Ind.* 1949 Dec. v 27 No 6, 235-9. English summary (6 lines).

During a period of nine years the author has observed 14 women who had clinical attacks of malaria before and after parturition. Eleven had *P. vivax* infection, three *P. falciparum*. None of the three infants born of mothers with *P. falciparum* infection showed any signs of malaria. Five of the 11 infants born of mothers with *P. vivax* malaria developed the disease very soon after birth—two within 40 hours, one on the fourth day, one on the fifth day and one on the seventh day. The infections in all 11 infants were very readily cured with very small doses of quinine. None suffered from relapse during a period of observation of more than a year. The cures were possibly spontaneous by reason of immunity acquired during gestation.

Norma Blake

CHEMFIPTOS S. Malaria tertiana in die Psychiatrische Klinik. (1929-1948). Tertian Malaria among Psychiatric In-Patients at Frankfurt 1929-48. *Nachricht. Psychiat. Grenzsch.* 1949 July 7 v 43 No 27 200-30. 1 graph. 13 ref. English summary (8 lines).

Since the beginning of the century tertian malaria has been prevalent among the psychiatric patients of Frankfurt in the northern part of the North Rhine. Between 1929 and 1948 1 326 patients were affected. There were 434 relapses in 334 patients. Numbers affected remained fairly constant up to 1941 when there was a sharp rise lasting up to 1946 in which year 34.7 per cent of the patients were affected. In 1947 the rate fell to 27 and in 1948 to 31 per cent. It was noted that an autumn peak always preceded a higher rate the following spring.

Clinically, cases were recorded in which onset of exacerbation of psychiatric symptoms coincided with an attack of malaria, often undiagnosed. In some cases, however, an attack of malaria was associated with an improvement in the psychiatric condition.

Various forms of treatment were employed. Quinine sulphate, 1 gm daily for seven or 14 days, resulted in 49.2 per cent of relapses. With atebrin [mepacrine], three tablets daily for seven days, there were 39.3 per cent of relapses and two cases showed psychotic symptoms. The majority of patients received "chinoplasmine", three tablets daily for 7, 14 or 21 days, giving relapse rates respectively of 52, 9.7 and 1.7 per cent. There were a number of complications, including various cardiac side-effects, few of them serious and mostly associated with pre-existing cardiac damage.

The most satisfactory therapeutic agent was "Kinplex", a Dutch preparation containing 150 mgm quinine sulphate and 9 mgm pamaquin per tablet. With a dose of six tablets a day for 14 days there were no relapses at all in 51 patients treated and no complications or side-effects.

A. L. Winner

BROUNST, G. Présence de *Plasmodium ovale* à Beyrouth (Liban) [*Presence of Plasmodium ovale in Beirut (Lebanon)*] *Bull Soc Path Exot* 1949, v 42, Nos 5/6, 257-9

A case of *Plasmodium ovale* malaria is described from Beirut, Lebanon. A female child was brought for examination and was found to be ill-nourished and anaemic, and to have enlargement of the liver and spleen. Numerous schizonts of *Plasmodium ovale* were present in the blood. Treatment with quinine for three days followed by mepacrine for five days cured the child whose general condition was much improved. The parasites were diagnosed by examination of drops of blood stained with Giemsa's stain; they were in the stage of large schizonts, surrounded by Schuffner's dots, visible in spite of the loss of haemoglobin in the thick drop, and were said to be very typical of this species.

[The diagnosis of *Plasmodium ovale* in a thick drop from a locality where the infection has not been reported before is open to some criticism, even well-stained thin films are not always easy to diagnose. The parasites were stated to be oval in this infection—it is usually thought that a crucial diagnostic feature of *Plasmodium ovale* is the round parasite in an oval erythrocyte. The author states himself that *ovale* malaria is extremely benign, and yet this case presented symptoms of some severity which were ameliorated by antimalarial treatment.]

COOPER, W. C. Summary of Antimalarial Drugs. *Pub Health Rep Wash* 1949, June 10, v 64 No 23 717-32 [101 refs.]

This short article on antimalarial drugs contains no new information but has been written in an attempt to clarify the confusion, which the author rightly believes to exist in the medical literature, with respect to those substances synthesized in the last few years. At different times they have been referred to by a number, synonym or under a proprietary name. All the compounds dealt with namely, quinine, totaquine, quinacrine [mepacrine], chloroquine, oxychloroquine, sontochin, camoquin, paludrine [proguanil], pamaquin, pentaquine and isopentaquine have received mention in this *Bulletin* with, as a rule, some synonyms in brackets. In the case of quinacrine no fewer than twelve additional names are mentioned in the present article. Constitutional formulae, dosage both therapeutic and suppressive, synonyms, behaviour in

the body activity and indications for use are briefly described. For the treatment of acute attacks of malaria the author states that quinine, quinaquine, chloroquine or other 4-aminoquinolines or paludrine are adequate. He believes that for this purpose chloroquine is the drug of choice and like paludrine is a good suppressant. For relapsing benign tertian infections the value of quinine in combination with one of the above 8-aminoquinolines is recognized.

J. D. Fallon

FIELD, J. W. Modern Anti-Malaria Drugs. *Med. J. Malaya* 1949 Mar v 3 No 3 173-90 8 figs. [33 refs.]

This summary of the characteristics of some of the synthetic anti-malaria drugs that have proved their worth should be of great value to practitioners and malaria workers who have not ready access to the vast literature dealing with the subject. The drugs dealt with are atebryn [mepacrine], paludrine [proguanil], chloroquine, santonchin, plasmoquine, pentaquine, camoquin and metachlorondine. The chemical structure of each of these remedies is graphically described as is their mode of action, therapeutic and suppressive dosage, elimination and toxicity. The full list of synonyms of each of these drugs is particularly useful. The relative costs of treating an acute attack of *falciparum* malaria with quinine, atebryn, paludrine and chloroquine for seven days, respectively, are illustrated in graphic form, as are the costs of suppression with these drugs, per person per year. The comparison is based on present wholesale prices in Malaya.

An addendum summarizes some recent reports on paludrine-resistant strains of *P. falciparum*. Such strains have not yet been reported in Malaya. For the treatment of attacks of *P. falciparum* malaria, 300 mgm. of paludrine daily for 7-10 days are recommended, reinforced on the first day only with 600 mgm. of atebryn in two doses of 300 mgm. or with 2 gm. of quinine in 4 divided doses.

Norman White

BLACK, R. H. Observations on the Treatment of *Falciparum* Malaria. *Trans Roy Soc Trop Med & Hyg* 1949 May v 42, No. 6 593-8 6 figs. on pl. and 1 chart. [13 refs.]

The object of this short paper was "to outline a rational view of the present treatment of *falciparum* infections in the light of our present knowledge of the mode of action of antimalarial drugs."

Intravenous injection of paludrine, proguanil has been used for the treatment of cerebral malaria. Paludrine acts upon trophozoites only at the stage of earliest chromatin division. In cerebral malaria parasites harbored within the cerebral capillaries are in the later stages of development; much time will be lost if paludrine is the only drug used in the treatment of such a case.

Quinine and atebryn (mepacrine) arrest the development of *P. falciparum* early in the asexual cycle. Quinine should be used in the treatment of cerebral malaria as well as in heavy infections with *P. falciparum*. The strains of the species of parasites of both human and bird malaria differ among themselves in their response to antimalarial drugs.

The best treatment for a good therapeutic response in severe *falciparum* infections is the intravenous injection of 10 gram. of quinine dihydrochloride in solution, given over a period of 10 minutes. This should be followed by oral paludrine. In debilitated patients with thrombocythemia the intravenous injection may have to be given more slowly, by drip infusion, for example.

FAIRLEY, N H The Efficacy of Paludrine (Proguanil) as a Therapeutic Agent (West African and New Guinea Strains of *Plasmodium falciparum*) [Correspondence] *Trans Roy Soc Trop Med & Hyg* 1949, May, v 42, No 6, 623-6

COVELL, NICOL, SHUTE and MARYON recently reported failure to cure patients infected with a West African strain of *P falciparum* with a single course of paludrine [proguanil] [this *Bulletin*, 1949, v 46, 703] They suggested that the high rate of radical cure obtained with paludrine by FAIRLEY *et al* at Cairns may have been due to delayed treatment In the Cairns experiments, however, paludrine treatment was instituted at various intervals after exposure to infection, from the time sporozoites first entered the blood on the seventh day till several weeks after the onset of overt malaria The author thinks that delayed treatment, with development of partial immunity, was not responsible for the radical cure obtained The extreme sensitivity of the New Guinea strains of *P falciparum* to the schizonticidal action of paludrine was shown by the facts that a single dose of 100 mgm paludrine often resulted in clinical cure and the temporary disappearance of asexual parasites in non-immune volunteers, a high incidence of radical cure was obtained in both natural and experimental infections by the administration of 0.1 gm paludrine thrice daily for 10 days, asexual erythrocytic parasites disappeared from the blood during such a course of treatment in 2.1 to 2.35 days

The discordant results must be attributed to differences between two distinct geographical strains of *P falciparum* New Guinea is situated well within Wallace's line, so perhaps it is not surprising that its strains of plasmodia have special characteristics

RUHE, D S, COOPER, W C, COATNEY, G R & JOSEPHSON, E S Studies in Human Malaria XII The Protective and Therapeutic Action of SN 5241 against St Elizabeth Strain Vivax Malaria *Amer J Hyg* 1949, May, v 49, No 3, 346-54, 6 figs

SN 5241 is α -(dinonylamino-methyl)-1,2,3,4-tetrahydro-9-phenanthrene-methanol It is a close analogue of NIH-204 (SN 1796) which was found to have insufficient antimalarial activity [this *Bulletin*, 1948, v 45, 147, 150]

Twenty-one prisoner volunteers were the subjects of this inquiry, they were infected by the bites of *Anopheles quadrimaculatus* with the St Elizabeth strain of *P vivax* SN 5241 hydrochloride was given in capsules each containing 0.25 gm of base The usual dose was 1.5 gm a day The drug was shown to have antimalarial activity, but its action is slow It does not permanently prevent or cure vivax malaria During 18 courses of therapy two patients developed severe maculo-papular skin reactions and a third had mild urticaria. Two of 10 subjects undergoing protective tests also developed skin reactions It did not produce the undesirable side-effects that SN 1796 does but the high incidence of cutaneous reactions precludes its routine use
Norman White

COOPER W C, RUHE, D S, COATNEY, G R & JOSEPHSON, E S Studies in Human Malaria XIII The Therapeutic Action of Metachloridine (SN 11,437) against St Elizabeth Strain Vivax Malaria *Amer J Hyg* 1949, May, v 49, No 3, 355-60, 2 figs [15 refs]

This records the attempted cure of 10 prisoner volunteers who had been infected with the St Elizabeth strain of *P vivax* by mosquito bite They were all treated during late attacks, occurring more than six months after infection

Their early attacks had been suppressed by either quinaquine (mequacine), santonchin or chloroquine. Blood smears were examined at least once weekly until 18 months after original exposure to infected mosquitoes.

SN 11 437 (metachloridine) a sulphonamide was administered in capsules each containing either 0.25 or 0.5 gm. of the drug. Five patients were treated with SN 11 437 alone. For delayed primary attacks the dosage was 0.5 gm. every six hours for 12 days. In the treatment of second or third attacks the dosage was raised to 4.0 gm. a day sodium bicarbonate was given concurrently with the larger doses and doses were at times reduced so as to maintain plasma concentrations at about 14 mgm. per 100 ml. There was slow clearance of patent parasitaemia, average 6.2 days; subsidence of fever averaged 3 days. Relapses occurred after 3 of 5 initial late attacks and after one of 3 second late attacks; parasites reappeared in the blood 22 to 58 days after the end of treatment. One patient on the third day of the second course developed a petechial rash of the lower limbs.

In a second series of five cases the SN 11 437 in doses as above was reinforced with 2.0 gm. of quinine sulphate a day. The response was what might have been expected from quinine alone. Relapses occurred after all five of the initial courses of treatment at intervals of from 31 to 46 days. No further activity followed second courses. One of these patients also developed a purpuric rash on both legs during the second course.

It may be concluded that SN 11 437 has serious deficiencies which make it unlikely that it will become a generally useful antimalarial.

RENE D. S. COOPER, W. C. COATNEY G. R. & JOHNSON E. S. Studies in Human Malaria. XIV. The Ineffectiveness of Colchicine (SN 12,000) SN 7266 and SN 8557 as Curative Agents against St. Elizabeth Strain Virus Malaria. *Amer J Hyg* 1949 May v 49 No 3 361-63 figs. [13 refs.]

Colchicine (SN 12,000) SN 7266 (the ethyl ester of β -guanylfenazone acid) and SN 8557 (3-(decahydro-2-naphthyl)propyl 3-hydroxy 1,4-naphthoquinone) all failed to prevent relapses when administered after quinine sulphate treatment of attacks of St. Elizabeth strain *P. m. malaria*.

Norman H. Ayle

RENE D. S. COOPER, W. C. COATNEY G. R. & JOHNSON E. S. Studies in Human Malaria. XV. The Therapeutic Action of Pamaquine (Plasmochin) against St. Elizabeth Strain Virus Malaria. *Amer J Hyg* 1949 May v 49 No 3 367-73, 1 fig. [19 refs.]

Twenty-three subjects with late primary attacks of *P. m. malaria* St. Elizabeth strain were treated with pamaquin naphthoate and quinine sulphate. Relapse was observed in one patient out of four who had had 0.03 gm. (dose) of pamaquin a day for six days after a six-days course of quinine sulphate 2.0 gm. a day. No relapse occurred among 19 patients who were given 0.03, 0.06 or 0.09 gm. (dose) of pamaquin a day concurrently with 4 gm. of quinine sulphate a day for 1 day. These results contrast with a relapse rate of 80 per cent. when late primary attacks of this strain of *P. m.* are treated with non-curative drugs such as quinine, quinaquine, mequacine, chloroquine, santonchin or metachloridine.

GARCIA E. J. The Inhibition of Malarial Relapses by Tarsolol of Chloral, m. *Ann. Reprinted from A. New York Acad Sci* 1949 June 7 50 Art. 3, 171-86, 4 figs.

A chance observation of a remarkable case prompted the investigation described in this paper. A mental patient undergoing malaria therapy in the

U S A. developed gas gangrene, a *Clostridium welchii* infection. The *P vivax* parasitemia disappeared spontaneously the day after the onset of gangrene, and malaria parasites did not reappear. When the author returned to the Philippines he decided to ascertain whether the allied tetanus toxoid possessed any antimalarial activity.

Three hundred and nineteen patients suffering from malaria were treated and observed for 330 days. They all received a basic treatment which consisted of an intramuscular injection of 0.10 gm atabrin [mepacrine] followed by the oral administration of either 2.1 gm atabrin or 3.5 gm chloroquine during a period of seven days. Sixty-five of these patients, 40 with *P vivax* and 25 with *P falciparum* infections, received no further treatment. Thirty-six, 90 per cent, of the *P vivax* patients had parasite relapses, as had 21, 82 per cent, of the *P falciparum* patients. The average interval to relapse was 115 days.

The remaining 254 patients (193 *P vivax*, 61 *P falciparum*) each received, at the end of their basic treatment, a subcutaneous injection of 1 cc tetanus toxoid in the deltoid region. This was repeated three weeks later. None of the *P falciparum* and only 15 (7.7 per cent) of the *P vivax* patients so treated had a parasite relapse. The average interval to relapse was 315 days. The author suggests that the toxoid stimulates the phagocytic activity of reticulo-endothelial cells.

GARNHAM P C C. Malarial Immunity in Africans. Effects in Infancy and Early Childhood. *Ann Trop Med & Parasit* 1949, Apr, v 43, No 1, 47-61, 2 text figs & 2 figs on pl [33 refs]

Most of the observations recorded relate to a single African tribe, the Luo, living around the Kavirondo gulf of Lake Victoria, East Africa, a highly malarious region.

Congenital malaria was not observed among 146 infants born of mothers infected with malaria, with one possible exception, a case of *P malariae* infection which is described. Malarial infection rarely resulted in still-birth or in the death of the infant during the first week of life. The Luo infants are born free from malaria parasites and are unlikely to suffer ill effects from infection in the mother. From a third to a half of Luo children are likely to acquire *P falciparum* infection during the first six months of life, all are infected during the first year. A quarter of the infants acquire *P malariae* infection during the first six months, and nearly all during the first three years of life. The incidence of *P vivax* infection is patchy. The parasite rate during the first two months of life was only 10 per cent, this low rate is possibly explained by transmitted passive immunity.

Malaria among these children was clinically a mild disease, only 10 per cent of cases were severe. The temperature rarely rose above 100°F, convulsions were rare.

Seventy-five children were examined periodically for two years with special reference to the effect of the malaria infection. It caused little deterioration of general physique. Fever was slight and unaccompanied by convulsions. The normal increase in weight was uninterrupted during the first attack of malaria in a third of the children, in the remainder the weight remained stationary or there was a slight loss. The red-cell count was lowered by 13 per cent during the first attack but after five months of continued malaria infection the count had returned to normal. Six of the children died, only one from malaria. Each child received only 30 to 60 grains of quinine throughout the whole two years.

Post mortem examinations were made of 3 infants whose blood had shown malaria parasites and who would normally have been certified as having died from malaria. Malaria was the cause of death of only 17 of the 52. Meningitis, pneumonia and gastro-enteritis were among the causes of death of the others. Malaria in infants is characterized by an unusually massive lymphoid macrophage response to the infection. In the liver the proliferation and swelling of the Kupffer cells is excessive. The blood vessels are encorged with lymphoid-macrophage cells in all stages of development. Throughout the body the swollen and proliferated endothelium interferes with the blood supply as much as do clumped parasitized erythrocytes.

No evidence of exocerythrocytic schizogony was found in brain, heart, liver or spleen.

Malaria in early childhood must be studied against a background of immunity—phylogenetic transmitted passive and acquired immunity.

Norman H. Aik

GARNHAM I. C. C. *Modern Concepts in Malaria Control*. J. Roy. Soc. Med. 1949 Sept. 1, 69 No. 3 817-23 [30 refs.]

The modern insecticides have transformed the situation in regard to malaria control, but they have not made the older methods obsolete, and it is still wise to drain swamps and trim streams. Nevertheless the insecticides have made possible programmes of control or eradication which would have seemed impossible by the older methods. The author gives an interesting account of his own work on the control of epidemic malaria in the Kenya highlands where *Anopheles gambiae* transmits the disease seasonally. The use of DDT in the houses of an African population of 10,000 in a tract of country covering 60 square miles at 8,000 feet was responsible for a distinct fall in parasite rates and an even more impressive fall in numbers of *A. gambiae* caught in houses. Comparisons were made with neighbouring untreated areas, which unlike the treated country were swept by malaria. A more clear-cut result would probably be obtained if a bigger tract were treated.

The author writes very favourably of dimethyl phthalate as a repellent.

Garnham discusses, in a very brief section, the subject of immunity, when he writes: 'it is difficult to underestimate the importance of immunity in any tropical Africa (one knows what he means)'. In the hyperendemic areas of Africa the adults do not suffer from malarial fever and the children and infants show little evidence of its effect. The death rate from malaria of infants has probably been much exaggerated: the author performed post mortem examinations on 52 infants (of various tribes) all supposed to have died of malaria but he found that this was the true cause of death in only 17, the rest having died of undiagnosed meningitis, pneumonia, etc. (see also GARNHAM above). Garnham then postulates the effect of incomplete control in a hyperendemic area: infection would be reduced to perhaps one or two infective bites per annum instead of hundreds and the result would be gradual loss of immunity and if control were subsequently slackened devastating epidemic of malaria might occur. This kind of event has been postulated before but the reader may ask whether it has, in fact, actually happened. Garnham has himself stated that if the infants and children in a community do not suffer severely from malaria 'it may be because of an in-born immunity, not merely a passive immunity derived from their mothers during the first few months of life'. If this is true it is not easy to foresee how devastating an epidemic would be. Constant infection no doubt creates the state of premunition but it does so in people already considerably endowed with in-born resistance. In time of course the reduction of infection would

permit survival of less immune individuals, and the community as a whole would become more susceptible to the disease, but this process might be very slow]

The author makes the point that in hyperendemic areas it would be advisable to consider whether large sums of money could be more usefully employed on the provision of water, prevention of soil erosion, and other measures, rather than on malaria control. He advocates further research into the alleged grave effects of the disease in hyperendemic areas [The reviewer entirely agrees that this research is needed. He also thinks that an experiment is needed to discover just what will happen if incomplete control is established in a hyperendemic area]

Charles Wilcocks

CIUCA, M., ALEXA, I., DUPORT, M. & ATHANASIU, M. Efficacité et limites de la chimiothérapie dans un programme systématique de lutte antipaludique. Recherches effectuées au cours d'une épidémie fulminante à *P. falciparum* [Efficacy and Limitations of Chemotherapy in a Systematic Anti-Malaria Campaign. Research undertaken during a Violent *P. falciparum* Epidemic.] *Arch Roumaines Path. Expér. et Microbiol.* 1948, v 15, Nos 1/2, 199-224, 15 figs & 7 graphs (4 folding)

Disorganization occasioned by war was in part responsible for a very serious epidemic of malaria in the Tulcea District of Rumania. The Tulcea District lies between the lower reaches of the Danube and the Black Sea coast. It has a population of about 120,000. *Anopheles clutus* [*sacharovi*] and *A. maculipennis atroparvus* are both prevalent. Malaria endemicity was high in 1939. Epidemic outbreaks occurred in 1940-1942 as the result of the colonization of non-immune settlers, without adequate protection. The *P. falciparum* epidemic afflicted the immigrant and indigenous populations alike. In 1938, 82 per cent of positive blood films contained *P. vivax*, 17 per cent *P. falciparum* (8,300 examined). In 1946, 12 per cent were *P. vivax*, 84 per cent *P. falciparum*, and 3.4 per cent *P. malariae* (16,011 films examined). The malaria death rate in 1946 was 210 per 100,000.

The organization set up to combat the deplorable health conditions that the epidemic had brought to light comprised a polyvalent Health Centre in the town of Tulcea in constant liaison with 36 rural health centres, newly created, a mobile dispensary containing a diagnostic laboratory, 2 antimalaria stations, and a malaria diagnostic and treatment centre at Isaccea. The Tulcea Hospital and rural district hospitals gave medical assistance. The medical staff included 12 health officers, 8 specialists, 1 bacteriologist, 2 entomologists, 41 health visitors, 15 midwives, 24 sanitary inspectors, and 20 drug distributors. Voluntary organizations also rendered assistance, notably the Rumanian Red Cross Society who provided 23 additional nurses and antimalarial drugs received from the League of Red Cross Societies. The effort achieved remarkable success as evidenced by the vital statistics that are produced. The infant mortality rate during the first half of 1948 was 60 per cent lower than in the corresponding half of the previous year.

In 1943, *A. m. atroparvus* and *A. sacharovi* were prevalent along the coast and *A. m. messeae* was predominant in freshwater breeding places in the Danube Valley and in the north-west of the district. In *A. sacharovi* areas the infection rate (sporozoites and oöcysts) averaged 2.64 per cent. *A. sacharovi* was found for the first time in the Danube Delta at Sulina in 1948, the extension of this species in the delta might have grave consequences.

The height of the malaria epidemic was in the autumn of 1946. In October of that year some 15,500 cases were recorded and the monthly incidence continued above 13,500 for the rest of that year. A constant decline in incidence

did not occur till October 1947 consequent upon the systematic treatment of patients and parasite carriers. The treatment consisted of seven days atabrin (mepacrine or its equivalent followed, after an interval, by five days of plasmoquine. It is estimated that 80 per cent. of new patients and those with relapses were so treated. After 18 months of such treatment epidemic waves were suppressed, malaria mortality was reduced by 83 per cent. and endemic index by 68 per cent., the proportion of *P. falciparum* infections fell to 25 per cent. a normal proportion for Rumania.

The authors insist however that, in the circumstances prevailing drug treatment is not enough: they recommend in addition the spraying of dwellings with a residual insecticide in regions of such high anopheline density. A small experiment with DDT spraying has been made with promising results.

Norman H. Aik

WALLACE R. B. Mass Suppression with Chloroquine. Chloroquine and Pentaquine and Neo-Premaltin. *J. Trop. Med. & Hyg.* 1949 May 52, No. 5 83-106 6 charts & 3 maps.

The experiments described were carried out on a rubber estate in Malaya of over 10 000 acres. Surrounded on three sides by jungle-covered hills, it is typical *A. maculatus* country with ravines, seepages, streams and drains with clear running water. All the eight divisions of the estate are malarious, some hyperendemic. Before Japan entered the war anti larval measures were carried out under strict control but did not prevent the seasonal epidemics of malaria that occurred with unflinching regularity. Suppressive treatment with atabrin (now mepacrine) was tried in the worst malarial divisions from 1932 onwards and continued until the war with Japan. It proved to be the most effective measure of control so far tried in that area. Now mass suppression of malaria with drugs is the only control measure used. It is more effective and cheaper than antilarval measures in this particular area. The latter never prevented seasonal epidemics: atabrin did. The newer insecticides are now on trial, however.

The experiments described were largely confined to Indian members of the mixed population: they are more amenable to discipline and take drugs more readily than the Malaya, Chinese and Japanese. The population of each division was divided into two groups, X and Y. Group X was given the new drug, Group Y a harmless placebo. The year 1948 was an unfortunate one for the experiment. The early high prevalence of *A. maculatus* indicated severe malaria epidemic to follow, but unusual high storms that lasted fortnight occurred when the *A. maculatus* curve was at its height and caused a rapid fall in the prevalence of the vector. No malaria epidemic ensued, except in one area in which chloroquine was being tried. There was an unusual and unexpected increase in malaria prevalence in July-August.

Chloroquine diphosphat tablets were used, each of 0.3 gm. (containing 0.15 gm. base). They were given once a week, the dose varying from one-tenth of a tablet for infants under six months to two tablets for ages 14 years and over. There were 100 persons in Group X and 53 in Group Y. The drug, given from March 2nd to June 1st. There was complete protection for the group on suppression. There were no toxic effects. During April 40 per cent. of the control group were admitted to hospital for malaria. Thereafter the control group also received chloroquine. Most of the cases that occurred in June, July and August were from the original control group. When atabrin was used as a prophylactic there was always a marked rise in the malaria rate some three weeks after medication ceased. After chloroquine there were only three cases in the first month: one subtertian and two benign tertian.

Chloroquine and pentaquine were given in tablets, each containing 0.15 gm chloroquine base and 0.015 gm pentaquine base the dosage was the same as for chloroquine [these doses are given in terms of base only] Group X contained 158 and Group Y 137 persons. The drugs were given from March 2nd to June 1st and from July 30th to October 1st. In this area the expected epidemic did not materialize, there were no cases in May. In June and July when an unusual wave of malaria occurred there were 1 and 19 cases in Group X, and 12 and 20 in Group Y. At the end of July both groups received treatment, all available labour was then needed.

The test was not a severe one, but chloroquine and pentaquine gave complete protection. In April there were seven cases in the control group and none in Group X. The fall in malaria incidence in August was remarkable, only one case occurred. There was no case in September among the treated, among the Malays there was a 5 per cent incidence. There were no toxic effects of any importance.

Neo-Premaline was given in tablets, in the case of two divisions. Each tablet contained chloroquine base 0.15 gm, pamaquin base 0.0075 gm, and rhodoquine base 0.0075 gm [doses given in terms of base only]. The dosage was the same as for other drugs. In Division H Group X contained 123 and Group Y 109 persons. The drugs were given from March 17th to June 30th. In April the malaria rate was 6 per cent in the control group, there was no case in the treated group. During the whole period there were 19 cases from Group Y, one from Group X. The parasite rate in Group X fell from 7 per cent to nil. In the control group it rose to 20 per cent then gradually fell to 5 per cent in June as the malaria wave receded. There were no toxic effects from the drugs.

The results obtained with all three drugs were impressive and warrant further trial.

Norman White

CHWATT, L. J. *Anopheles gambiae melas* Control by Swamp Drainage in a Coastal Zone of Nigeria, British West Africa. *Mosquito News* 1949, June, v. 9, No. 2, 56-68, 4 figs. [15 refs.]

Coastal swamp drainage as a means of permanent control of the breeding places of *Anopheles melas* was carried out by Dr. A. B. GILROY between 1942 and 1947 at Lagos in Nigeria and is fully described in his monograph "Malaria Control by Coastal Swamp Drainage" [this *Bulletin*, 1948, v. 45, 1043]. The author of the paper under review reiterates these methods and tabulates annual results till 1947 in terms of average *Anopheles* density index (*melas* only) in two typical zones, contrasting figures of daily anopheline larvae collections per acre of water surface in drained and undrained swamps are quoted, e.g., 28.4, 1,734.8.

By the end of 1946, approximately 20 miles of embankment had been constructed to exclude sea-water from a total swamp area of 4,195 acres, associated "internal" drainage amounted to a length of 130 miles and 21 sluice gates were necessary. By this means the town and harbour works of Lagos (pop. 200,000) have been almost cleared of *Anopheles melas* as evidenced by a fall in average *Anopheles* density in the port zone from 47 *melas* per room in 1942 to 2.2 for the worst quarter of 1947. Contrary to expectations, little breeding of *melas* occurs in the drains, larvae may be found in pools caused by temporary obstruction, over 50 per cent of larvae are first or second instar, and pupae are rare, cyclical rise and fall of water level and the presence of larvivorous fish are important factors. Constant vigilance by the Government Malaria Unit is essential.

The author categorically rules out the use of residual insecticide (DDT) as a sole measure of control of *A. opifera* *melas* under these conditions because "there are only few human habitations within or in the vicinity of the main breeding area." The value of reclaimed land is an important side issue. The author believes the results attained in the Lagos area justify the use of coastal swamp drainage even though more modern methods of control are available.

LIVDORF, H. Crustacea copépodes comme ennemis naturels de larves d'anophèles. [Copepods as Natural Enemies of Anopheline Larvae.] *Bull. Soc. Path. Exot.* 1948 v. 4, No. 58, 178-9.

NAIR, C. P. Investigation on DDT Barrier Spray in Malaria Vector Areas in Malaya. *Med. J. Malaya* 1949 June v. 3, No. 4 250-58.

In 1945 in the township and outskirts of Klang four sites, each of which included a control, were selected to test the residual action of 5 per cent DDT in kerosene on the local malaria vectors, *A. maculatus*, *A. letifer* and *A. sundanensis*. On the first occasion spray was applied in atomized form to the interior of dwellings to the outer surfaces of walls and to vegetation etc., covering a surrounding zone fifty yards in width measured from the perimeter of the site. Interior space spraying was not included in subsequent sprayings and the later sprayings towards the end of the four-month test period were applied to the protective 50-yard barrier only. The quantity of spray used per acre on any one site remained the same irrespective of the surfaces treated and was approximately five gallons. Early in the test period the appearance of any mosquitoes was the signal for re-spraying but subsequently the occurrence of anophelines only was followed by a repeat treatment. From his observations the author concludes that the period after spraying for a build-up of mosquitoes to 10 per cent of normal population is 10 days on the outskirts and 1 day in the town or for anophelines 13 and 15 days respectively. Return to normal of the general mosquito population occurred after six weeks. The best results were obtained by the barrier spray only without the use of any of the fixed quantities of insecticide in treatment of the dwellings.

[From the tabulated data the reviewer finds the above-quoted assessment of results difficult to follow.]

R. Ford Treloar

TETELAFF, F. Malaria Control Progress and Problems. *J. National Malaria Soc.* 1949 June v. 3, No. 2, 115-20 3 figs.

The programme for the elimination of malaria from the U.S.A. within the five years beginning in 1947 depends on Federal and State participation. There has been a steady increase in State activities which now makes their contribution about equal to that of the Federal authorities. As a result of this and the favourable progress of the campaign it has been possible to modify the criteria on which areas are considered malarious and requiring treatment making them much more stringent than before.

In 1948 the number of houses treated was 1,374 '66 the usual treatment being a single season application of DDT at a rate of approximately 200 mgm. per sq. ft. (7 oz. per 100 sq. ft.) of wall and ceiling surfaces in homes on the back and inside of furniture on front and back porches and in privies. *A. quadrimaculatus* are now found in 8 per cent of sprayed houses which compares with 1.0 and 1 per cent in 1946 and 1947 when more frequent treatments were given. The number of cases of malaria is not stated.

There have been complaints that fly control has not been as satisfactory as in previous years which is explained partly by fly resistance and partly by the manner in which refuse is handled and possibly by unsatisfactory DDT concentrates. This is regretted because fly control is an important means of securing local co-operation.

A number of alternative insecticides have been tried out, but DDT as it is now being used is still the most effective and most economical one available.

GAHAN J B, DOWNS W G & CLISS H. Control of *Anopheles pseudopunctipennis* in Mexico with DDT Residual Sprays applied in Buildings. Part II. *Amer J Hyg* 1949, May, 49 No 3, 285-9.

In a previous paper [this Bulletin, 1947, 41, 880] encouraging entomological results were recorded in the initial stages of the use of residual sprays (1945) in villages in Mexico where the vector of malaria, *A. pseudopunctipennis*, breeds in rice-fields. The application of DDT either in emulsion or wettable powder form was continued through 1946, 1947 and 1948, and when checked the dosage was 238 milligrammes per square foot. Internal wall and roof surfaces of all dwellings and other buildings were treated once each year. Adult mosquitoes collected in houses have been reduced to very small numbers (e.g., 92 to 0.5 per house) but this method of checking offers little proof of lethal effect: mosquitoes are seldom found dead in buildings, suggesting that they leave after contact with a lethal surface. Special emphasis was therefore attached to estimation of larval abundance in the rice-field. Average counts of *Anopheles* larvae obtained by dipping are tabulated for each month of the three years 1945, 1946 and 1947, the counts having been made on approximately the same date each year. For example at one village untreated in 1945 the average number of larvae per dip for all observations in 1945, 1946 and 1947 were 3.44, 0.61 and 0.28 respectively. It is evident that the DDT applications did not kill enough adult mosquitoes to reduce the breeding in the surrounding rice-fields, but the continued presence of larvae after three years of residual insecticide application does not suggest that this sole method of control will eventually eradicate *A. pseudopunctipennis* from these localities. Laboratory tests were carried out to determine whether resistant strains of anophelines had developed after four annual sprayings: there was no evidence of such strains. The effect of this work on malaria incidence is to be reported later.

GIGLIOLI G. Mosquito Eradication. [Correspondence] *Brit Med J* 1949, Sept 10, 595.

Dr Giglioli in reference to a leading article in the *Brit Med J*, 1949, July 23, 222 on mosquito eradication gives a salutary reminder that measures of malaria control whether by means of residual insecticides or by older methods, cannot be effective or economically sound unless they are applied with an intelligent knowledge of local epidemiological conditions. Especially important is the study of the bionomics of the local vectors: results obtained in Cyprus, Sardinia and British Guiana are cited to show that their significance is strictly limited to the local vector and ecology.

With the use of residual spraying methods, a knowledge of breeding habits is not enough: the feeding, biting and resting habits of the adult insects must be thoroughly understood. Anthropophilic and domestic species (e.g., *Anopheles darlingi* and *Aedes aegypti*) are specifically vulnerable to residual techniques and have been eradicated by these methods alone in settled areas of British Guiana, under a wide range of environmental conditions which are fairly typical of a large part of tropical South America. On the other hand, mosquitoes which bite in the open and do not enter houses, such as *A. bellator* in bromeliads in Trinidad

can be expected to be as refractory to residual spraying as they are to conventional hydrological control.

Between these extremes are species which are only partly domestic and anthrozoophilic in their biting habits, e.g. *A. albimanus* and *A. aquasalis*. With these, residual methods only give partial results: those mosquitoes actually entering houses can be eliminated, and malaria transmission thereby reduced, but the total species population will hardly be affected. Residual house-spraying has had no effect whatever on the population of *A. aquasalis* in British Guiana.

While localized eradication of *Aedes aegypti* and *Anopheles darlingi* has been achieved under continental conditions in British Guiana, the possibility of re-invasion remains if periodical application of DDT is not continued indefinitely. Nevertheless with adequate local topographical and ecological knowledge spraying operations can be confined to a number of strategic localities and advantage taken of natural barriers to different species: even under continental conditions, natural obstacles may be found and exploited, through a complete knowledge of the biology of local vectors and local environmental conditions.

The author's main thesis is contained in his wise observation: "Generalizations in the malariological field are no more warranted to-day than they were yesterday: before the introduction of residual insecticides."

DE MELLO, P. J. & PIROO, O. da S. Contribuição à melhoria do equipamento para desinfestação domiciliares. [Improvements in the Methods of Insecticidal Spraying of Houses.] *Rev. Brasileira Malariologia*. Rio de Janeiro, 1949 Apr. v. 1 No. 2, 100-102, figs.

Two improvements in methods of treating houses with residual insecticidal spray are described. (1) For spraying numerous rooms in large buildings it is convenient to use a petrol compressor which supplies compressed air along a lead to an insecticide container which is taken into the building (apart from if necessary). The container is a 30-litre cylinder which carries 15 litres of DDT solution and a 15-litre air space for compressed air (at 25 lb. per sq. inch). Several keels can be taken off this container allowing men to operate simultaneously from the same supply. (2) For purposes of estimating quantities of spray required, it is desirable to measure the surface area of rooms to be sprayed. Two simple instruments enable this to be done very rapidly. (a) An extensible rule is used to find the height of the ceiling. (b) To obtain the perimeter a wheel of suitable size fixed in a revolution counter is run round the walls of the room. The product of perimeter and height give a rough guide to surface area.

D. aplicação extradomiciliar de DDT por helicóptero no combate aos anofelinos do subgênero *Herzianus* em matas primárias com predominância de bromélias epífitas. [Application of DDT and Benzene Hexachloride by Helicopter in the Attack on Anophelines of the Sub-Genus *Herzianus* in Forests where Epiphytic Bromeliads predominate.] *Rev. Brasileira Malariologia*. Rio de Janeiro, 1949 Apr. v. 1 No. 2, 62-69, 1 graph, 16 refs.
- II. FERREIRA, M. O., RACIOL, R. C. & DE BUSTAWANTE, F. M. Da aplicação extradomiciliar de hexaclorobenzeno por meio de helicóptero no combate aos anofelinos do sub-gênero *Herzianus* em matas primárias com predominância de bromélias epífitas. *Ibid.* 69-69, 3 figs.
- i. In the state of Santa Catarina malaria is transmitted by Anophelines of the sub-genus *Herzianus* which breed in the axils of bromeliads. In some areas

where the bromeliads are terrestrial, malaria control can be done by destroying all the plants of this type in the neighbourhood of the towns. But in other districts, the bromeliads are epiphytic, in dense natural forest, and their destruction is very difficult. This paper records attempts to destroy the mosquitoes and the larvae breeding in the bromeliads by dusting DDT over the forest from a helicopter.

A Bell model 47 helicopter was used, weighing 691 kgm and capable of carrying 130 kgm of insecticide (or up to 180 kgm on short flights, by reducing the fuel carried). A 10 per cent DDT dust called "Gyron" (Geigy Co, Brazil) was employed. Applications were made to two test wooded areas of 100 and 30 hectares respectively.

The effects of treatments were judged by the following observations made before and after treatment in the test woods and in another control wood about 30-40 km distant —

(1) Night catching at 4 or 5 human baited traps per wood. This indicated effects on adult mosquitoes.

(2) Larval density per bromeliad was determined by searches at intervals, and also special observations were made on larvae placed in marked bromeliads shortly before treatment.

The results of applications of 900 gm DDT per hectare (13 oz/acre) gave a reduction of adults from 92 to 99.8 per cent (as compared with observations before treatment) for 25 days after application. The effect on larvae was only 77 per cent reduction at 24 to 48 hours but the numbers subsequently declined owing to the high kill of adults. Treatment with DDT at 1,300 gm per hectare (19 oz/acre) in another wood gave 90.3 per cent reduction in adults, reaching 78 to 100 per cent at 16 days after treatment. The kill of larvae was better, being 94 per cent (one day) and 98 per cent (one week) after treatment.

ii. Similar experiments were carried out with gamma BHC preparations. A dust "Gamorial" containing 1½ per cent gamma isomer (Duperial Co) was applied at the rate of 150 gm active principle per hectare (about 2 oz/acre). This gave a 99.23 per cent reduction of adult mosquitoes on the second night after treatment. For four days the population of *Kerteszia* remained low but after six days, reinfestation began to be evident. This treatment had no appreciable effect on larvae.

A treatment with "Agroside" containing 6½ per cent gamma isomer (Duperial Co) in 10 per cent aqueous suspension was made at the rate of 156 gm active principle per hectare. This reduced adult mosquitoes by 86 to 100 per cent from the second to twelfth day, but reinfestation began to be appreciable thereafter. Unlike the powder treatment, the "Agroside" reduced the larvae by 90 per cent on the third day after treatment.

[The large percentage reductions in the tests reported in these two papers are partly offset by a substantial natural decline over the period of the experiment e.g., adults captured in the control wood showed a reduction of 23 to 94 per cent (average 70 per cent) as compared with the period before treatment.]

RUSKIN, A & RIGDON, R H. The Electrocardiogram of Normal and Malaria-Infected Monkeys. *J Lab & Clin Med* 1949, Aug, v 34, No 8, 1105-8, 1 fig.

' 1 The normal electrocardiogram of the *Macaca mulatta* monkey is between that of the dog and man. The variability includes negativity of the T waves in Leads I, II, and IV F, and displacement of the S-T segments from the iso-electric line.

" 2 The electrocardiogram of malaria-infected *Macaca mulatta* monkeys does not differ from that of the controls in the great majority of instances. The rare

exceptions include marked (left) axis deviation and slight prolongation of the Q-T interval. No typically anoxicemic electrocardiographic changes were demonstrated even in monkeys showing red blood cell counts only 25 per cent of normal.

3 The absence of significant electrocardiographic alterations in monkeys infected with *P. knowlesi* is consistent with the known pathologic changes in malaria in monkeys and with the findings of others in a large series of cases of malaria in human beings."

LLOYD, O. C. & SOMMERVILLE, T. The Fate of Sporozoites of *Plasmodium cynomolgi* Injected into the Skin of Rhesus Monkeys. [Abstract.] *J. Path. & Bact.* 1949 Jan. v. 61 No. 1 144-6.

This paper summarizes the more important results of an investigation in monkey malaria [see this *Bulletin* 1947 v. 44 896]. The details of the work are given in a thesis by the first author for the Cambridge University doctorate of medicine. Mosquitoes infected with *Plasmodium cynomolgi* were ground in monkey serum and injected into the abdominal skin of Rhesus monkeys. Each monkey received two injections simultaneously, the inocula being the product of 50 mosquitoes. At varying periods (minutes, hours and days) the skin at the two sites was excised: one portion was prepared for section, the other was transplanted in a clean monkey. At similar periods blood was drawn from the infected animals and inoculated into others. Unlike the results of HOFF and COCHRAN's experiments with avian malaria (this *Bulletin* v. 1943 v. 4, 538) no local development of the sporozoites was detected. The sporozoites persisted in large numbers for two hours in that part of the skin which had yet to be invaded by inflammatory cells, viz. in the central liquid part of the inoculum. By four hours the sporozoites had vanished. The parallel experiments with subinoculated skin and blood confirmed these results—the monkeys developing malaria up to a maximum of two hours after having received these inocula. Subinoculations of blood taken at 20 and 40 minutes after the inoculations gave rise to infections in the recipients indicating that sporozoites were circulating in the donor's blood during this time. Under the conditions of these experiments it seems unlikely that sporozoites gained an entry into the blood before 20 minutes.

The authors conclude that many sporozoites are killed at the local site probably by the lytic action of phagocytes; others escape from the area probably by the lymphatics via the thoracic duct to the blood stream. Under natural conditions after the bite of an infected mosquito the sporozoites may either enter the blood stream directly after penetration of the proboscis into a capillary or via the lymphatic route. In the former case they will be demonstrable immediately (as in FAIRLEY's work see this *Bulletin* 1945 v. 4, 630) in the latter not until 20 minutes or so have elapsed (as in these experiments).

TALLAFERRO W. H. KELSEY F. E. TALLAFERRO LOYD G. The Role of the Spleen and the Lymphoid-Macrophage System in the Quinine Treatment of Gallinaceum Malaria. I. Acquired Immunity and Phagocytosis [TALLAFERRO W. H. *J. J. Res. Dis.* 1948 Sept. Oct. v. 83 No. 164-80, 4 figs. II. Quinine Blood Levels TALLAFERRO W. H. & KELSEY F. E. *Ibid.* 181-99 7 figs. III. The Action of Quinine and of Immunity on the Parasite TALLAFERRO W. H. & TALLAFERRO LOYD G. *Ibid.* 1949 Mar. Apr. v. 84 No. 2 187-220 10 figs. (Numerous refs.)

I. It is possible that in chemotherapy the importance of the part played by the host in combating infections and producing cures has been underrated.

An active role has however been assigned by some authors to certain body cells such as those of the lymphoid-macrophage system which are believed to act in conjunction with drugs. The theories expressing these beliefs are outlined by the authors as follows —

- 1 The drug acts chiefly, or in large part, by stimulating immunity
- 2 The drug indirectly kills the invading organism by an opsonin-like action which makes the parasite more easily phagocytosed
- 3 The drug is fixed or absorbed by the reticulo-endothelial system in such a way that its redistribution facilitates a longer drug-parasite contact
- 4 The drug is converted by the reticulo-endothelial system (or other tissue) into a more chemotherapeutically active metabolic transformation product
- 5 The drug inhibits reproduction of the invading organism which then becomes more vulnerable to the phagocytes or other defence mechanisms

The present investigation was designed to test these theories with special reference to the spleen, during the quinine treatment of *P. gallinaceum* infections of chickens and provided little or no support for them. The chickens used were kept on an alternate light and dark schedule for twelve hours and were infected by parasitized blood or sporozoites intravenously. Blood smears were examined once per day or more frequently during the course of the infection and the parasite counts were recorded per 10,000 red blood cells. Quinine dihydrochloride was given orally in capsules or intravenously according to body weight. Experimental results showed that splenectomy increased the mortality of treated and untreated chickens in comparable degree and indicated that the activity of quinine was not affected by this organ. Its removal lessened acquired but not innate immunity. The increase in acquired immunity produced by the spleen during infection is responsible for the crisis and subsequent low rate of parasitaemia. Observations on phagocytosis during the period of innate immunity in the case of blood-induced infections, treated with quinine indicated that the drug did not increase the phagocytic activity of macrophages of liver and spleen, which was marked, or those of bone-marrow which was much less intense. It appeared also that quinine did not make the parasites more easily phagocytosed, *i.e.*, possessed no opsonin-like activity. The results obtained during acquired immunity of blood- or sporozoite-induced infections led to conclusions similar to those above. Apart from the decreased phagocytosis associated with inhibition of parasitic growth and reproduction, histo-pathological studies failed to reveal any alteration in defence processes resulting from quinine treatment of the chicken host. The authors concluded that the spleen and the drug acted independently in suppressing infection.

II In this paper the mechanism whereby splenectomy appears to decrease the suppressive value of quinine in *P. gallinaceum* infection of chickens was investigated further by studying the course of infections in groups of splenectomized and non-splenectomized birds which did or did not receive quinine. In spite of the fact that quinine blood levels were raised and maintained for a longer time in the infected splenectomized chickens, the value of such increases was offset by the decrease in acquired immunity to which that organ gives rise. The rise in blood levels may have resulted from the infection *per se*, as earlier authors had found that for a given dose of quinine the concentration of the drug in tissues was frequently higher in infected than in non-infected chickens. On the other hand the rise may have followed splenectomy *per se* or, as also previously recognized, from the increased parasitaemia in absence of that organ with resultant more marked anaemia. There was a negative correlation between the quinine blood level and the number of red cells. The effect of quinine therapy on acquired immunity due to the spleen, as a result of specific and non-specific stimulation of that organ,

exceptions include marked (left) axis deviation and slight prolongation of the Q-T interval. No typically anoxicemic electrocardiographic changes were demonstrated even in monkeys showing red blood cell counts only 25 per cent of normal.

"3. The absence of significant electrocardiographic alterations in monkeys infected with *P. knowlesi* is consistent with the known pathologic changes in malaria in monkeys and with the findings of others in a large series of cases of malaria in human beings."

MITHROW KENNEDON, Lillie & KENNEDON, E. Die Entwicklung von *Plasmodium calhemum* im Erythrocyt und im Blut des Kanarienvogels. [The Development of *Plasmodium calhemum* in the Erythrocytes and Blood of the Canary.] Reprinted from *Zool. Jahrbücher (Anatomie)* 1949 Feb. 35 v. 70 No. 1 129-58 3 text figs. & 17 text. on foldin. pl. (28 refs.)

In this paper—which was completed in 1935—the authors give a detailed account of the entire exoerythrocytic (EE) development of *Plasmodium calhemum* in the canary. This is compared with *P. falciparum*—the life-cycle of which was previously (1943-1944) described by them in this *Bulletin* 1944 v. 41 190.

The infections in the forty canaries used in their experiments were in most cases produced by inoculating the birds intramuscularly into the breast with 0.2 cc. of a saline suspension of teased-up and filtered heads and thoraxes of infected *Culex* mosquitoes, each bird receiving about 1000 sporozoites. The study of the life-cycle of *P. calhemum* was based on stained organ and tissue smears of the birds sacrificed at various intervals after the infection.

The early stages of the development of this parasite occur at the site of inoculation of the sporozoites, whence they invade all the organs, but show a predilection for the spleen, liver, and especially the brain in which the EE forms are found in the endothelial cells of the capillaries.

After a latent period of several hours the sporozoites at the site of inoculation are taken up by reticulo-endothelial cells (macrophages, monocytes). In these they become rounded and proceed to multiply by schizogony; giving rise to 32 nuclei 30 hours after inoculation of which about 15 hours are occupied by the first nuclear division. The merozoites of the first generation again find their way into phagocytes which carry them to the inner organs, where they continue to develop in the endothelial cells. The schizonts of the first generation give rise to macromerozoites, which are larger than the merozoites of the erythrocytic cycle. In subsequent generations a minority of the schizonts produce small merozoites (micromerozoites) morphologically indistinguishable from those of the erythrocytic cycle. The macromerozoites of the second generation begin to enter the blood stream 63 hours after the inoculation of sporozoites. They invade the red blood corpuscles giving rise to both the asexual and sexual (gametocytes) forms of the erythrocytic cycle, while the endothelial schizonts continue to produce macromerozoites by which the EE cycle is maintained in the host.

The maturation of each generation from the 2nd onward occupies about 30 hours in the case of macroschizogony, and 33 hours in the case of microschizogony; the number of merozoites resulting from the former being from 33 to 64 and from the latter 63 to 124. As the infection proceeds the ratio of microschizonts to macroschizonts in successive generations rises progressively. After some time the number of parasites both in the blood and in the tissues begins to diminish and the infection may finally assume a chronic character with scanty parasites, but liable to relapse. The course of *calhemum* infection in canaries varies, being in some cases rapid, with a fatal termination after 9-12 days, while in others the infection passes into a chronic phase after 2-3 weeks.

The authors have demonstrated by blood subinoculation—that the merozoites derived from erythrocytic schizonts are capable of initiating the EE cycle in the recipient host, from which it would seem that the macromerozoites may give rise to macroschizonts in the tissues of the bird. The two cycles—erythrocytic and exoerythrocytic—are therefore interchangeable.

The brief summary given above does not do full justice to the very thorough and detailed account, accompanied by tables and graphs, given in this paper. It is illustrated by a number of photomicrographs and contains references to the literature appearing after 1944.

In an appendix the authors discuss the recent findings regarding the EE stages of development in mammalian malaria parasites. C A Hoare

TRYPANOSOMIASIS

FERREIRA, F S da C, PINTO, A R & DE ALMEIDA, C L. Sobre o grau de infestação por tripanosomas das glossinas da Guiné Portuguesa [Trypanosome Infection Rates of Glossinae in Portuguese Guinea] *An Inst Med Trop* Lisbon 1948, Dec, v 5, 251-61, 1 folding map. English summary.

The authors dissected 2,055 tsetse flies and found 140 (6.81 per cent) of them infected with trypanosomes as follows: *Glossina palpalis*, 65 infected out of 1,607 dissected; *G. submorsitans*, 42 out of 263; and *G. longipalpis*, 33 out of 185. Polymorphic trypanosomes were seen in 61 flies (2.96 per cent of the dissections) and monomorphic trypanosomes in 63 flies (3.06 per cent). *Trypanosoma grayi* occurred only in *G. palpalis*, 7 flies (0.34 per cent) and unidentified trypanosomes were seen in 9 flies (0.43 per cent).

[These percentages are based on the total number (2,055) of flies dissected and are given in the summary but not in the text. Percentages given in the three tables are misleading because they are calculated on the total number of infections for all three species of *Glossina*, not on the number of dissections for each species separately; the conclusions regarding the infectivity rates of these three tsetse flies are based on these erroneous percentages.]

TOWN, B W, WILLS, E D & WORMALL, A. Action of Suramin and "Antrycide" on Enzymes [Correspondence] *Nature* 1949, Aug 6, 233.

In a previous note the authors have shown [this *Bulletin* 1949 v 46, 914] that small concentrations of suramin exercise a strong inhibitory effect on hexokinase, urease, yeast carboxylase, succinic dehydrogenase and trypsin. Further investigation has confirmed that the inhibition of enzymes by suramin is relatively specific: some enzymes are inhibited only at particular hydrogen ion concentrations, and many are unaffected through the whole range of pH over which they act. Specific enzyme inhibition, deranging the trypanosome's carbohydrate or protein metabolism or both may account for the chemotherapeutic activity of suramin.

Although antrycide is very different from suramin chemically, the authors thought it possible that the two compounds might act in a similar way on some metabolic enzymes. They have found, however, that antrycide in relatively high concentrations has no inhibitory effect on urease, succinic dehydrogenase, the yeast enzymes concerned in the fermentation of glucose or on trypsin. Therefore, while suramin may perhaps act on trypanosomes by inhibiting carbohydrate metabolizing or proteolytic enzymes of these organisms, the mechanism of antrycide activity is probably different from that of suramin. BUXTON, P. A. Presidential Address on Control of Tsetse Flies by Human Settlement. *J. Roy. San. Inst.* 1949 Sept. & Oct. No. 5, 615-16.

In this short Presidential address the author introduced the subject in such a way that people not familiar with sleeping sickness work would be able to follow his reasoning. One important point is that the veterinary aspect of trypanosomiasis (and therefore indirectly the agricultural and medical aspects) is more important than the present low rate of spread of the disease in man. Loss of cattle from the trypanosomiasis means poor agriculture and therefore poor nutrition. A second point is that the settlements created in Tanganyika where the people have been concentrated, and from which *G. morsitans* has largely retreated, held 100 000 people in 1946—some of these settlements have been in existence for 20 years. The Anchar settlement in Nigeria is perhaps the most interesting public health experiment in Africa—it needed the combined efforts of medical men and entomologists together with those of persons who knew and took into account the African social conditions and agricultural customs (and modified them). Charles H. J. Cook

HENITT, R. I., GEMMEL, A., KUSH, R. S., SAPIR, S. R., BRANCO, F. L. M. & SHARON, Y. Experimental Chemotherapy of Trypanosomiasis. I. Effect of *p*-Phenylene Diguandine and Related Compounds against Experimental Infections with *Trypanosoma equiperdum*. *J. Pharm. & Exper. Therap.* 1949 July & Oct. No. 9, 305-14.

Among compounds examined since 1944 for chemotherapeutic effect against trypanosomiasis *p*-phenylene diguandine seemed worthy of detailed study. It was found to be curative for *T. equiperdum* infections in mice and rabbits but was much less effective than arsenicals, suramin or stilbamidine when administered parenterally. Given orally in divided doses over a period of 31 days, it behaved somewhat better. It was five times more effective than suramin and one-sixth as effective as stilbamidine. The ratio of curative dosage on oral treatment to curative dosage on intraperitoneal treatment was 500 for suramin, 120 for stilbamidine and 5 for *p*-phenylene diguandine.

Of closely related aromatic guanidines none proved more potent than *p*-phenylene diguandine.

No compound in this group exercised any action against *Leishmania donovani* in hamsters, *Schistosoma mansoni* in mice, *Leishmanolux* in cotton rat, *Plasmodium falciparum* in duck or *Trypanosoma cruzi* in mice. F. M. Lewis

VEGHEE, A., ROMÁN, J. & NORONHA, R. Nuevos datos sobre la enfermedad de Chagas en Chile. [New Data on Chagas's Disease in Chile.] *Boletín Sanitaria Panamericana* 1949 Aug. 28, No. 8, 808-17, 2 figs. (1 ref.).

The English summary appended to the paper is as follows:—

The authors present the results of investigations on Chagas' Disease in Chile up to June 30 1948. During systematic epidemiological surveys made of representative sample zones affected by endemicity 14 481 persons were examined, resulting in a 1.7% infestation by *T. cruzi*. From the Tarapacá to the O'Higgins provinces 1 724 proved negative; were found 10 036 complement fixation test were made which showed positive in 14.25%. The average index for trypanomatoma from the Tarapacá to the Coquimbo provinces is 44.1% for 20 842 samples of *T. cruzi*. Its endoparasites 10.9% (positivity) was found in 4 008 domestic and wild animal examined. There were 411 confirmed acute cases found in the provinces of Santiago and Antofagasta and 174 in the province of Coquimbo as a result of clinical investigations with special reference

to cardiopathy Prevention of Chagas' Diseases was attempted by the application of DDT in all the rural zones The application of 1,132 houses with DDT—5% in kerosene—showed that it was possible to control the breeding of the triatoma in 90% of the cases, with a low index of them up to 12 months later Success was also obtained by the use of gammexane in smoke-generators The authors mention the laws which are in force covering the prevention of the disease, as well as bills submitted to congress on rural dwellings and programs for future clinical investigations "

PELLEGRINO, J Transmissão da doença de Chagas pela transfusão de sangue Primeiras comprovações sorológicas em doadores e em candidatos a doadores de sangue [Transmission of Chagas's Disease through Blood-Transfusion] *Rev Brasileira Med* Rio de Janeiro 1949, May, v 6, No 5, 297-301, 1 fig [Bibliography] English summary

In Belo Horizonte, Brazil, Chagas's disease is fairly common and the vectors are abundant, nevertheless many doctors fail to recognize the facts and do not take sufficient care when blood-transfusion is called for As syphilis, malaria, relapsing fever and other diseases may be thus transmitted the author has investigated the question of the possible infectiveness of blood donors How rife the infection is is evidenced by the fact that among 8,142 unselected country-dwellers 1,383 (17 per cent) reacted positively to a complement deviation test Xenodiagnosis is far from infallible in chronic cases and it is these who show few or no symptoms and who might be selected as donors for blood-transfusion

The author has tested 179 blood-donors in the Belo Horizonte Transfusions Service He found two who were on the establishment and a third who was offering himself as a donor giving a positive complement fixation and two other volunteers were doubtful All those positive had lived in *Triatoma*-infested houses, two of them showed no symptoms of infection One who had given 300 cc of blood on more than one occasion and showed no signs of infection nevertheless gave a positive Guerreiro-Machado reaction twice

The author in consequence recommends that the blood of all prospective donors should be tested for complement deviation and any giving a positive or a doubtful reaction should be excluded and that, if blood is needed urgently, only those donors should be used who are definitely known to be uninfected

DE FREITAS, J L P & DE ALMEIDA, J O Nova tecnica de fixação do complemento para moléstia de Chagas (Reação quantitativa com antígeno gelificado de culturas de *Trypanosoma cruzi*) [New Technique for Complement Fixation in Chagas's Disease] *Hospital* Rio de Janeiro 1949, June, v 35, No 6, 787-800 English summary

For the diagnosis of chronic Chagas's disease serological tests are best, in fact almost necessary, owing to the difficulty of finding the trypanosomes Davis's antigen is good but is not very stable so that constant control tests are necessary The author's method of preparation has given a better antigen and he describes it as follows —

A culture on blood-agar is made with trypanosomes obtained from human cases of the disease, and is suspended in physiological saline and centrifuged at 2,000 r p m three times for 30 minutes each time, until the supernatant fluid is colourless This is decanted and volume of the residue noted This is then subjected to a temperature of -30°C and dried *in vacuo* at room temperature over calcium chloride, usually this takes about 48 hours The residue is ground

and benzene five times the tested volume of the deposit is added and left at room temperature with frequent shaking and exchanging for fresh benzene during another 48 hours. The supernatant benzene is then removed and the deposit dried at 37°C. for 12 hours. Distilled water to nine times the volume of the sediment is next added and left at room temperature with repeated shaking and then are added three volumes of chloroform which produces a jelly like mass. This is shaken with glass beads and in a Roemer's shaker distributed in quantities of 0.9 ml. in tubes and stored at -20°C. This retains its potency for three months or more and it is neither haemolytic nor anti-complementary. The author claims that the thromboplastic activity of the antigen is negligible.

The test has been made with 500 sera divided into three groups. 1. Those known to be suffering from Chagas's disease by finding the trypomastotes in the blood in the case of living patients or by xenodiagnosis or by finding trypomastote forms in the heart post mortem. There were 32 in this group. 2. Normal subjects or patients suffering from diseases other than Chagas's disease presumably 350 in number as the other groups together account for 140. 3. One hundred and eighteen suspicious cases suspicious either from presenting suggestive symptoms or living in a Trypanosom-infested locality.

In the first group one gave a negative result although the result was positive. In three others the readings were negative after four hours in the ice-chest but were positive after two hours at 3-6°C. followed by 30 minutes at 37°C. in a water-bath. The titres in all these ranged between 1/2 and 4/6. Of those in the second group none gave a positive with a titre above 1/4. Of the 118 in group 3, nine gave a positive in titre of 1/4-1/8 and 104 a titre between 1/8 and 4/8. From group 2 those with 1/4 or less are regarded as negative and from group 1 those above 1/8 may be considered as definitely positive and the only difficulty arises among those with a titre of 1/4-1/8 in these the test should be repeated after a few days.

DE BARROS, L. C. A electrocardiograma d forma crônica da moléstia de Chagas. [Electrocardiographic Changes in Chronic Cases of Chagas's Disease.] *Hospital Rio de Janeiro* 1940 31:3 33-35 15-30 18 figs. (18 ref.) English summary.

During the past five years, says the author, study of the electrocardiogram has been much intensified and the electrocardiographic picture has shown such variations that a full and detailed revision now was needed in order that one may know whether these tracings are peculiar to different phases of the disease or whether they may take on different forms in the sequelae.

The present study gives the results of such detailed study of 4 patients 3 of whom were shown to be genuine cases of the disease in that they all gave 3-plus or 4-plus reaction to the Michaelis-Ungerleider test. The findings and observations are and will be of the greatest interest to all cardiologists but are most of detailed interest for the general physician and the heart specialist. The heart disease is much more fully treated in this paper than in practice books in other countries. More than 170 changes were found and reproduced most of them unfortunately too small for study and these are discussed under the two main heads of irregular and ventricular complex. Each of these is again subdivided and the number of changes among the 47 patients are stated in percentages of the total for comparison. In the irregular complex group 4 or 8.5 per cent showed P waves of low voltage and 31.4 per cent (15) of high voltage or actual hypertrophy and 19 (47) had prolonged wave or more than 11 second QRS and other forms of wave a similarly considered of the ventricular complex 33 (70) had extrasystoles and other changes. All these are within well known limits in chronic

Chagas's disease between the normal and advanced myocardial disturbance, the most common being a "widened and irregular P, increased PR, QRS of the R B B B type and marked left axis deviation and fairly frequent polytopic ventricular extrasystoles" Those interested in more detail should consult the original

GOBLE, F C Chemotherapeutic Activity of certain 8-Aminoquinolines, particularly Pentaquine, in Experimental Chagas' Disease *J Parasitology* 1949, Aug, v 35, No 4, 375-8

Appreciable success in the treatment of *T cruzi* infections has so far been achieved only by compounds of the type of the quinaldine derivative Bayer 7602 (Ac) [MAZZA, COSSIO and ZUCCARDI, this *Bulletin*, 1937, v 34, 936], the trivalent arsenical Bayer 9736 (As) [MAZZA, BASSO and BASSO, *ibid*, 1943, v 40, 22], and certain phenanthridinium salts [BROWNING, CALVER, LECKIE and WALLS, *ibid*, 1946, v 43, 633]

It has now been found that certain antimalarial 8-aminoquinolines (the group to which pamaquin belongs) are active against *T cruzi* infections in mice For "screening tests" mice were infected by intraperitoneal inoculation of culture material, treatment being started four days later and consisting of intraperitoneal injections administered daily for five or six days For "evaluation tests" the duration of treatment varied in different experiments, and included both intraperitoneal and oral regimens Results were measured by the percentage of survivors and by the mean survival times Untreated controls usually died The compound which gave the best results among quite a small group of 8-aminoquinolines studied was pentaquine, a high percentage of cures being obtained whether treatment was by the intraperitoneal or the oral route

The author's opinion is that the potential usefulness of these pamaquin analogues in clinical practice is questionable in view of the known toxicity of the group as a whole

No action was discovered against *T congolense* or *T brucei* infections

PELLOUX, A & DECOURT, P Essai d'application pratique du SNP dans la lutte contre la maladie de Chagas [Trials in the Practical Application of SNP (Thiophosphate o'diethyl o'paranitrophenyl) for the Prevention of Chagas's Disease] *Bull Soc Path Exot* 1949, v 42, Nos 3/4, 114-16

The houses, treated in this experiment with SNP either as an emulsion or as a dust, were of wooden construction and gave ideal refuge to domestic parasites

Five rooms of one house were sprayed with a 1 per cent emulsion at the rate of 200 cc per sq metre Three rooms of another house were thoroughly dusted with 0.25 per cent "Rhodiatox" powder giving a deposit of 10 gm of powder per sq metre One room and a poultry house were treated with 0.5 per cent powder

SNP used either as an emulsion or as a powder killed *Triatoma*, *Argas persicus*, *Ornithodoros tolidos* and *Lyponyssus bursa*

The authors suggest that the dust is more effective where the house construction is poor and there are irregular planks and crevices, since the powder penetrates the interstices and remains effective for a long period An emulsion, on the other hand, is rapidly absorbed by the wood

SEN GUPTA, P. C. Treatment of Kala-Azar with Hydroxystilhamidine. *Lancet*, 1949 Jan 16 97-9 *69. 10 refs.]

Six cases of kala azar were treated by hydroxystilhamidine (4,4-diaminodimethyl-2-hydroxystilbene di-β-hydroxyethanesulphonate). This drug, synthesized by Dr A. J. ENI, several years ago had been found to compare favourably with stilbamidine in its *in vitro* and *in vivo* (in animals) action on *Leishmania* (this *Bull.* 1945 v 42, 19 1948 v 43 1128).

The patients were all Indians aged 10 to 45 and the diagnosis in each case was confirmed by the finding of *Leishmania*. Five had received no previous treatment. The drug was given only intramuscularly in four cases, only intravenously in one and by both routes in one. For the former route a 10 per cent. solution was used and for the latter the drug was dissolved in 2.5 ml. of 25 per cent. glucose and given very slowly.

The intention was to give two courses of 10 injections each on consecutive days with an interval of 7 to 10 days between courses amounting to a total of 3 gm. per 100 lb. body weight of patient but this course was modified in half the cases on account of severe local reactions. The average total was 2.7 gm. per 100 lb. body weight. The maximum individual dose given was 3.3 gm. per kgm. Smaller doses were given at first to test tolerance.

There were no untoward symptoms other than local inflammation at the site of the intramuscular injections. All six patients were apparently cured.

The usual clinical criteria of cure were observed during or at the conclusion of the course of treatment, namely: cessation of fever, improvement in general health and gain in weight, shrinkage of the spleen, pronounced improvement in the leucocyte count and a rise in the haemoglobin level in every case.

The six patients were followed up for 3, 3, 4, 7, 7 and 7 months respectively after the completion of the treatment and were found to be free from symptoms of kala azar. L. I. Vajpayee

CORRADETTI, A. Studi sulla epidemiologia della leishmaniosi cutanea della regione del medio Adriatico. II. Osservazioni sulla biologia del *Phlebotomus perniciosus* con. Studies on the Epidemiology of Cutaneous Leishmaniasis in the Adriatic Coast of Italy. II. Observations on the Biology of *P. perniciosus*. *Riv. di Parassit.* Rome 1949 June v 10 No. 2 111-16. English summary (* lines).

In a part of the Abruzzi all houses (rural and urban) have been treated with DDT at 2 gm. per square metre of wall and ceiling. *Phlebotomus perniciosus* generally became very rare. They seldom bit man indoors though they occasionally did so in the open.

In areas not treated with DDT these insects attacked man in the open as in such numbers as have perhaps not been recorded elsewhere in the world. They could always be found abundantly in stables and houses. P. A. H. I. M.

ORTIZ I & PARRA L. E. Presentación de un caso de *Leishmania truncataria* multiple con lesiones lepromatoides. Multiple Cutaneous Leishmanial Lesions resembling Leprosy. *Rev. de La Asoc. Méd. de Los Andes*. Caracas 1949 June v 15 No. 2 70-73. 4 refs.

The condition presented was illustrated by photographs. The patient showed numerous small nodules on ears, nose, arms, shoulders, flat along the chest, but there was no open lesion. By scarification or by staining lymph after speepering with I crystals as when examining for *M. lepro* the other found *Leishman Donovan* types in large numbers. In short it was a case of generalized cutaneous leishmaniasis. H. H. de C.

FEVERS OF THE TYPHUS GROUP

FONSECA, F & WOHLWILL, Fr *Tifus exantemático*

This book is reviewed on p 1195

PETRIE, P W R *Epidemic Typhus in Southwestern Arabia* *Amer J Trop Med* 1949, July, v 29, No 4, 501-26, 9 figs

The author gives a somewhat discursive description of his experiences in an effort to control louse-borne typhus which he found occurring in epidemic form during the years 1939-43, in the hilly region of the Yemen in South-West Arabia, near the Aden Protectorate

From references contained in the paper it appears that the places affected were at altitudes of 4,000 feet and upwards. In the capital, San'a the average mean shade temperature during the three months, October to December, is said to be 57°F as compared with 75°F during the same period in Aden

There must have been ample opportunities for the introduction of infection into the low-lying torrid areas of South Arabia, but neither typhus nor louse-borne relapsing fever appears to have become established in any of the coastal zones of the country

John W D Megaw

KRYNSKI, S *Investigations of Strains of Proteus X Type cultivated from the Organs of White Mice and House-Mice infected intranasally with Rickettsia prowazeki, the Causative Organism of Typhus Fever* *Bull Inst Marine & Trop Med, Med Acad, Gdansk, Poland* 1948, v 1, No 1, 29-32

The author has carried out a series of serological and biological investigations, "still incomplete", into strains, believed to be of *Proteus X* which were isolated from the organs of mice inoculated intranasally with *Rickettsia prowazeki*

Such strains were never found in healthy mice and the conclusion reached is that the occurrence of the strains is "explainable by a dissociation of *R. prowazeki* which in mouse organisms passes into a non-virulent form of *Proteus X*"

John W D Megaw

PHILIP, C B, TRAUB, R & SMADEL, J E *Chloramphenicol (Chloromycetin) in the Chemoprophylaxis of Scrub Typhus (Tsutsugamushi Disease) I Epidemiological Observations on Hyperendemic Areas of Scrub Typhus in Malaya* *Amer J Hyg* 1949, July, v 50 No 1, 63-74 [20 refs]

This paper consists of a detailed description of the epidemiological conditions prevailing in three areas near Kuala Lumpur in which scrub typhus occurred in hyperendemic form

Area I was part of a rubber plantation in which the mature trees had been cut down by the Japanese in 1943 and the ground had become overgrown with weeds and shrubs. In the work of clearance 37 out of a gang of 80 Tamil workers were attacked by scrub typhus between December, 1947 and July, 1948

Area II had been primary jungle which was cleared by the Japanese for growing food crops, but had later become overgrown with grasses. Among 17 persons engaged in cutting grass in the area ten were attacked by scrub typhus

Area III consisted of abandoned vegetable gardens which had become overgrown with *alang* grass. Nearly 100 Japanese internees were attacked by scrub typhus while engaged in cutting grass in late 1946

In none of the above areas had scrub typhus been known to occur before the Japanese invasion

There was suggestive, though not conclusive, evidence that relapses occurred more frequently among the patients whose treatment was started early

Eight of the volunteers had been inoculated with the British (Karp) type of vaccine prepared in 1945, and two had received relatively fresh vaccine of the American type, there was no evidence that either vaccine had any protective value, and it is stated that the American vaccine has recently been shown to be useless in Japan

The only suggestion of toxicity of chloromycetin was the occurrence of a moderate degree of insomnia in some cases after 4.0 gm doses. One patient said that he had felt the same degree of euphoria after a 4.0 gm dose as after a dose of 2.5 mgm of benzedrine

The authors discuss the similarity of the prophylactic effect of chloromycetin to that of mepacrine in *vivax* malaria *John W D Megaw*

HILDICK-SMITH G Tick-Bite Fever Report of a Case treated with Aureomycin.
South African Med J 1949, Aug, 20, v 23, No 34, 702-3, 1 fig

Tick-bite fever, caused by a rickettsial organism, is common in Southern Africa and may have serious complications

The author reports, with clinical details, a case of tick bite fever in a European male of 36. The case was clinically characteristic and was confirmed serologically

It was decided to administer aureomycin and this was given orally firstly in dosage of 250 mgm. at intervals of one hour for three doses, so that a high tissue concentration of the drug could be obtained. The dose was then repeated five times at intervals of two hours, after which the temperature became normal. The interval was then increased to four, six and finally eight hours. Therapy was stopped after a total of 4 gm had been given

The patient became afebrile in 14 hours, free from symptoms in 24 hours and was normal in 72 hours

The author points to the need for more studies of cases of tick bite fever so that the optimum dose and intervals may be determined. He refers to the two cases treated by GEAR and HARRINGTON [this *Bulletin*, 1949, v 46, 1025]
H J O'D Burke-Gaffney

ROSENKRANZ, G Queensland Fever in Israel Harefuah Jerusalem 1949
Aug 15, v 37, No 4 [In Hebrew 37-41, 5 figs (12 refs) English summary 41]

Q fever has already been detected in Israel [this *Bulletin*, 1949, v 46, 1026]. The present authors saw increasing numbers of cases of epidemic primary atypical pneumonia, without atelectasis in most cases, and with no cold agglutination

As Q fever was suspected, specific complement fixation tests were made and in 40 cases, titres of 1/32 to 1/2,054 were found. In some the titre rose fourfold during the disease. There were 220 patients in all of whom only 20 were in-patients

The clinical, radiological and other features are described. All but two cases examined radiologically showed lung involvement usually in the lower lobes

The temperature remained raised for five to 30 days (one case in the latter instance) with an average of ten to 12 days. Bradycardia was usually present. The only complication noted was orchitis, which occurred in one patient on the tenth day. There were no deaths directly attributable to the disease.

H J O'D Burke-Gaffney

ARMOUR A. & GILDMAN L. Isolation of the Causative Agent of Q Fever
C. burnetii in Israel. *Harefuah* Jerusalem, 1949, Aug. 15 37 No. 4.
 [In H. (rev. 41-3 English summary 43.)]

In connection with the outbreak of Q fever in Israel referred to, the authors succeeded in transferring the disease from the blood of a human case to guinea-pigs and isolating *C. burnetii* from these animals in egg inoculation. This organism was passaged and recovered successfully in other guinea-pigs.

The incubation period in guinea-pigs after the first inoculation of human blood was eight days; the incubation period was shortened during five serial passages. In guinea-pigs a rise of temperature was the only manifestation of the disease.

So far seven serial passages have been made in eggs. In the first the embryos died in seven to ten days, but after the third passage they died in five to six days. From the third passage onwards numerous exfoliations were found in areas of the yolk sac.

Guinea-pigs infected with an emulsion of yolk sac developed a severe and fatal form of the disease with many sick tissues in areas from the internal organs.

H. J. O'D. Burke-Gaffan

LEVETTE E. H. CLARK W. H. & DEAY H. H. Sheep and Goats in the
 Epidemiology of Q Fever in Northern California. *Am. J. Trop. Med.*
 1949 July v. 23 No. 4 527-41 2 figs. 22 ref.]

The first detection of the occurrence of Q fever in North California was made by a serological survey in March 1948. It appeared that cattle did not play an important part in the epidemiology of the disease, but that goat and sheep were specially concerned.

In one district with 200,000 cattle and 824,000 sheep there were 150 proved cases of the disease between March and October 1949. In 20 per cent. of the cases there was close contact exclusively with sheep and goat, and in 50 per cent. contact was only with cattle.

Cattle were encountered in only five of the 18 sites in which human cases occurred. In the remaining sites sheep or goats were the only animal with which the patients had been in contact. Complement fixation tests were carried out on 707 cattle of the affected area, and only 8 per cent. gave positive reactions, whereas 37.9 per cent. of the sheep and 43.6 per cent. of the goats reacted.

Sera from slaughter houses gave positive reactions in 7.1 per cent. of cattle and in 3.5 per cent. of sheep; these animals had not been specially worried with the occurrence of human attacks and the findings were regarded as being the low prevalence of infection in the region as a whole.

In the course of a limited survey the most striking results were obtained from five sheep belonging to a ranch in which 80.9 per cent. of the sheep were serologically positive. From one of the sheep with a complement fixation titre of 1-312 Coombs (Killett or *C. burnetii* var. 1) dated from the milk. The organism was also isolated from a pooled sample of the milk of 10 goats of the same ranch in which 3.4 per cent. of the goats gave positive reactions.

The mode of transmission is not known; swallowing infected milk and inhalation of infected dust are possibilities; transmission by tick must be exceedingly rare.

Reference is made to the investigation carried out by Coombs et al. who isolated the organism from the milk of sheep and goats in California. See this Bulletin 1949 v. 23 No. 2.

YELLOW FEVER

KOMP, W H W A Note on Disease-bearing Mosquitoes breeding in Bromeliads
Mosquito News 1949, June, v 9, No 2, 72

On several occasions Komp has collected larvae and pupae of *Haemagogus argyromeris* from water in the leaf-bases of a terrestrial Bromeliad, *Bromelia pinguin*, and once in an arboreal Bromeliad (*Gravisia* sp.), in the Panama Canal Zone. Other species of *Haemagogus* transmit yellow fever in jungle country, but they have hitherto been found breeding only in tree-holes, bamboo, etc. The new finding may have an importance in relation to the spread of yellow fever. Moreover, certain unidentified Sabethines were found breeding in terrestrial Bromeliads, and female adult *Haemagogus urialeti* were captured which could only have bred in them.

In a note on the same page F C BISHOPP reports the first outbreak of yellow fever in Panama since 1905. This occurred at the end of 1948, and there were five fatal cases near Pacora. The outbreak was terminated by prompt and widespread immunization.

Charles Wilcocks

RABIES

ORTIZ MARIOTTE, C Rabia humana en Mexico [Rabies in Man in Mexico]
Medicina Mexico 1949, July 10, v 29, No 583, 255-61

The date when rabies was first found in Mexico is not known, but an Anti-Rabies Institute was inaugurated in 1888. During the next 40 years the classical Pasteur method was used, but since then Semple's method or some modification of it. A table shows the numbers of deaths from rabies in each of 32 districts for each of the 10 years 1938 to 1947, the total was 410, the lowest, 23, in 1940, the highest, 66, in 1946, and the average 40. The sex was noted in 362 dying in the period 1938-1946, and 235 (64.9 per cent) were males, 127 (35.1) were females, although a population census shows a preponderance of females. The ages of those dying are given, 18 were under one year, 16 between 1 and 4 years, 62 between 5 and 9 years, 42 between 10 and 14 years, 19 between 15 and 19 years, and then in successive decades 97, 72 and 35, the age of one was not known. It is stated that "23% of the deaths were not medically certified", but that the histories in these were reliable. More detailed figures are given for the years 1945 to 1948. Of 66 deaths (said to be 30 per cent of all deaths registered during this period as due to rabies) 37 were males, 29 were females, bites were on the lower extremities in 25, on the head in 16, on the upper limb in 13, 17 of those dying were in the third decade, 11 were in the sixth decade. In 25, treatment by vaccine was started within 48 hours of infliction of the bite, in 3 it was later than this, in 8 the vaccination was "irregular and interrupted", and 30 received no specific treatment. During the period 1945 to 1947 altogether 4,008 persons received vaccine treatment and it is estimated that at least 83 per cent of those bitten by animals certainly rabid escaped death from the disease. Nearly all those bitten received some treatment on the spot, either direct cauterization, application of corrosives, disinfectants, or suction of the wound. The interval between infliction of the bite and starting the vaccine treatment is given for the period 1945-47 in percentage figures: less than 1 day 19.2, 1 to 4 days 60.72, 5 to 7 days 23.6, that is, more than 86 per cent received the treatment within a week. By far the most bites are inflicted by dogs, 3,867, as compared with cats which come next with 62, rats are third (stated as 27.3). The question of immunization of dogs is to be studied.

HAUTE ET J. CON. LANTIER, A. & TOME, A. Recherches expérimentales sur la rage. (Experimental Studies in Rabies.) Arch. Roumaine Path. Expt. et Microbiol. 1946 v. 13 No. 1-2, 133 pp. (37 refs.)

HORMAN ET AL. & COX, H. R. Studies on Chick Embryos adapted Rabies Virus. I. Culture Characteristics and Pathogenicity. J. Immunology. 1946 Dec. v. 60 No. 4 533-51 1 fig. (21 refs.)

The authors have adapted four rabies strains (Flury, NY, Zillwood and Dixon) to the chick embryo. They found seven-day-old embryonated eggs to be optimal and the best time for harvesting to be between the ninth and eleventh day after infection. Infections titre seemed to depend somewhat on incubation temperature.

Another experimental series dealt with the virus distribution in eggs. Titres proved to be nearly identical in the central nervous system, the body and the chorio-allantoic membrane, slightly lower in the yolk sac and very much lower in the allantoic and amniotic fluids if harvested on the seventh day. Titres in these fluids when harvested on the eleventh day were however almost as high as elsewhere. From this distribution the conclusion is reached that the virus must be not neurotropic as was proved for mammals but haemato-genic. Other work by the same authors now under publication on the infectivity of the blood from the chick embryo confirms this view.

A further experimental series was designed to answer the question: what influence if any, has the amount of original inoculation on the final titre. Inocula $10^{1.0}$ cc. (dilutions 10^1 to 10^8) gave equally good results. The same volume of 10^4 dilution of the original embryo suspension (containing approximately 20 M.I.U.) gave a poor yield. These findings are of much interest because of the fact that they do not confirm those of Henle in respect of the influenza virus which with almost dilutions as inoculum gave the optimal results.

The pathology of rabies infection of the chick embryo has been tentatively considered. The weight of infected embryos was found to be about 1/20th of that of normal embryos and seemed to depend directly on the amount of the original inoculum.

Eggs when infected with the very dilute virus were also found to be infected on the seventh day, never later but they died usually prior to hatching. Some 14 days after infection an outcome affected neither by the route of the inoculation route (intracerebral, yolk sac or amniotic). When the virus was carried out later however there was a latent time of 10-12 days before an increased proportionality. The latent death with the very dilute virus took place 7 days after hatching. Later deaths preceded by paralysis were virus-free.

The virus was used for serological studies. Neutralising titres were found regularly from the 1st day on. Latent time and titre were in the same order up to the 15th day. The question as to whether or not such was due to latent infection with rabies thus arose. The following results showed the virus only up to a maximum of 1st day. Heretofore.

The last of the experimental sections in the paper under review dealt with the determination of changes in virulence for the bird virus. Several series of pieces of adapting the virus to the chick embryo. But it first of all involved inoculation with the Flury strain followed by a latent period of 7 to 20 days after which they frequently succumbed within the first week. Several series and were all dead in 1-3 hours. Peripheral inoculation gave no positive results in rabbits. However, highly susceptible mice were used regularly when inoculated with material up to the 15th day. First of all

Flury strain, later passage material tended to leave survivors that were but temporarily paralysed. Hamsters were invariably killed by the 30th passage level of the NYC strain. Guinea-pigs appeared to be more refractory to peripheral infection with egg-adapted strains, inasmuch as the incubation period was extended up to 10 to 14 days and death occurred in 15 to 19 days after infection. In guinea-pigs there was no case of spontaneous recovery. *G Stuart*

JONNESCO, D & STAMATESCO, Silvia. L'action antibiotique de culture du bacille mésentérique sur le virus rabique fixe [The Antibiotic Action of *Bacillus mesentericus* on Rabies Fixed Virus] *Arch Roumaines Path Expér et Microbiol* 1948, v 15, Nos 1/2 302-4

The idea for the experimental work described in this article came from the observation that wounds from rabid animals which heal quickly give rise to the disease in a higher proportion of cases than do wounds which suppurate for a prolonged period. Culture media filtrates from staphylococci and streptococci, as well as from *P. pyocyaneus*, failed to reveal any power of neutralizing rabies virus, but with *B. mesentericus* the authors consider a virucidal action to have been established. [The conclusions are based on the use of only one animal per experiment. The culture fluid (stated to be a simple beef extract) would not appear to have been tested for possible virucidal properties. The titre of the inoculation virus was not determined.] *G Stuart*

BUSSARD, A, BEQUIGNON, R & LAMY, R. Contribution à l'étude de la rage III. De la présence de hyaluronidase dans la bave de chien normal [Contribution to the Study of Rabies III. On the Presence of Hyaluronidase in the Saliva of the Normal Dog] *Ann Inst Pasteur Hygiène* 1949, Aug, v 77, No 2, 183-5 [Summary appears also in *Bulletin of Hygiene*]

Articles I and II of this series have been previously reviewed [this *Bulletin*, 1949, v 46, 728]. In the present paper the authors describe a series of tests carried out with a view to proving that the saliva of normal dogs contains hyaluronidase. To this end they employed the measurement of viscosity reduction of a purified ammonium hyaluronate solution with a Couette type viscosimeter. Comparative tests with the Ostwald type provided similar results. Conventionally one V R unit was equal to 20 minutes.

The dogs were injected with 0.05 gm pilocarpine, of 14 tested as above only two dogs showed no hyaluronidase in their saliva, the rest showed up to 154 units per cc. Boiling for more than five minutes completely destroyed the enzymatic action, while storage at +5°C for two months led to a great reduction of activity.

From these results the authors conclude that the hyaluronidase content of the saliva enhances the virulence of the rabies virus and enables it to traverse the connective tissue and reach the nerve endings. *G Stuart*

VITTORIO VANNI, D. Nuevo método de coloración de los corpusculos de Negri [A New Method for Staining Negri Bodies] *Semana Méd* 1949, Aug 11, v 56, No 32, 263-5, 1 fig

The new method is a modification of that of Neri (1909). Neri's original method consisted of fixing the tissue in acetone and embedding in paraffin, sections were stained for ten minutes in 1 per cent eosin containing 0.1 gm of iodine and 0.2 gm of potassium iodide, after washing in water the section was stained with 0.1 per cent methylene blue for five minutes, then decolorized

to a lilac colour with 85 per cent alcohol. The Negri bodies stain a red colour, the cytoplasm blue with nucleoli dark blue but the results were inconsistent because of the decolorization by alcohol which takes place quickly.

The author modifies this in the following way. The fixative used is some form of osmotic sublimat. Lepane Zenker formal-sublimat etc. The tissue is then stained in double strength Lugol's iodine (iodine 1 gm. potassium iodide 2 gm. distilled water 100 cc.) and 1 per cent eosin mixed in equal parts immediately before use the stain being allowed to act for 30-45 minutes then washed in distilled water and stained with 0.5 per thousand methyl (not methylene) blue for three to five minutes for counterstaining washed, dehydrated and mounted as usual.

The Negri bodies take on a brilliant ruby-red the nerve and glia cells a cobalt blue. Methylene blue is a basic stain and will not colour decomposed cells or those which have undergone chromatolysis for it is the turned body which takes the methylene blue. methyl blue is an acid stain and so stains decomposed or chromatolyzed cells. The Negri bodies are easily distinguished from the red corpuscles (they are not by the original Negri method) because the latter take on a brick red colour in contrast with the ruby-red of the Negri bodies.

PART C 1 & 2. JERVIS H. F. Rabies Vaccine Encephalomyelitis in relation to the Incidence of Animal Rabies in Los Angeles. Amer J P H 53 1949 July & 39 No 7 875-7

The authors report on nine cases (one fatal) of neuro-paralytic accidents which followed antirabies treatment with a Semple type vaccine (20 per cent rabbit brain either extracted, plasma-inactivated) among 5,500 persons vaccinated in Los Angeles during the seven years period 1940-46. Such an incidence of 1 in 600 is among the highest recorded. 1/4 (or 1 in 600) HORRICK 1 in 1,200 the Bulletin 1931 28 25 1834 39 731

Other interesting figures given are in respect of 3,180 persons between 1912-47 bitten by dogs proved to have been rabid at the time of wounding. Of that number eight died of rabies in spite of vaccination and 14 died without having been vaccinated.

As reckoned from these statistics the chances are 1 among 180 bites reported to be from a rabid animal and from 1 in 1,400 to 1 in 100 that a bitten person contracts rabies.

Animal passage experiments from all fatal cases of neuro-paralytic accidents were as is to be expected consistently negative. But as the previous allergic history of the patients are not provided. Emphasis is laid on the danger of the vaccine in the absence of a vaccine free from paralytic provoking factors. It is especially considering in each case whether or not and how much vaccine should be administered.

JERVIS G. A., HORNBERG R. L. & JERVIS H. Demystifying Encephalomyelitis in the Dog associated with Antirabies Vaccination. Amer J P H 53 1949 July & 39 No 1 14-21 8 Apr. 4th rels.

The purpose of this article was to report four cases of neuro-paralytic illness in dogs after antirabies vaccination. In their accidental attempt to produce neuro-paralytic accidents in these animals the authors administered to each of a group of 100 dogs (50 of the St. Bernard and 50 of the Great Pyrenees breeds) which had previously been immunized by the LaSalle-Dunkin method against distemper over a period of 100 cc of a 20 per cent horse brain emulsion with 0.5 per cent plasma antirabies vaccine. In 10 of 100 dogs a therapeutic

four dogs—all of the Great Pyrenees breed—developed paralytic symptoms. Of these, three were sacrificed when moribund and one, which had shown signs of partial paralysis on the 20th day after vaccination, survived, but still had, three months later, a residual paralysis, spastic in type, of the hind leg

A detailed pathological examination was carried out on two of the dogs and nine photomicrographs (eight figs) are published. Perivascular infiltration with lymphocytic and histiocytic elements, demyelination and gliosis were the main changes observed. Attempts to isolate the infectious agent by means of repeated subinoculations failed, and it is of interest to note that in no instance, on complement-fixation testing with rabbit and dog brain as antigen, were anti-brain antibodies demonstrated. Thus although the virus origin of the condition was experimentally excluded, its possible allergic nature could also not be proved, inasmuch as anti-brain antibodies, such as have been detected in the guinea pig, were not found.

Demyelinating encephalomyelitis giving similar histological lesions may occur spontaneously in the dog and has been observed in the nervous form of canine distemper. Very interesting parallels to human encephalopathies are drawn, viz, the spontaneously occurring type—acute multiple sclerosis, the post-vaccinal type—following vaccination and anti-rabies treatment, and the post-infectious type—following measles or mumps. G Stuart

SABBAN, M S EL. Cultivation of Pseudorabies Virus in the Yolk Sac of the Developing Chick Embryo. *Proc Soc Exper Biol & Med* 1949, July, v 71, No 3, 423-9, 4 figs

In this paper the growth of the pseudorabies virus (Aujeszky) on the yolk sac membrane of the chicken egg has been studied. Seven-day-old embryonated eggs used in the investigation were harvested immediately after death, which took place at first on the third day and at later passage levels in 40 hours. The yolk sac membrane was found regularly to provide an infectious titre of 10^6 , while the embryonic tissue and the chorio-allantoic membrane and fluid gave a titre one log lower except at first egg passage, when they titred only 10^3 . During adaptation of the virus to the chick embryo mortality rose gradually from 60 per cent at the first passage to 80 per cent after the fifth passage and to 100 per cent from the twelfth passage on.

After the fiftieth egg passage, the virus failed to produce any skin lesions in the subcutaneously-infected rabbit, but, as commonly happens after intracerebral inoculation, paralytic symptoms made their appearance.

A detailed description of the pathology of the disease in chick embryos is given. Macroscopically, haemorrhages occurred, at the higher passage levels, over the entire skin surface. Microscopically, congestion and leucocytic infiltration of the brain, together with all stages of degeneration of central nervous tissue, were found. Mesothelial cells of the brain as well as the yolk sac membrane showed acidophilic intranuclear inclusions which were at first only in the form of granules but in later passages solid.

For the identification of the virus, a neutralization test with antiserum of known activity against rabbit-brain passage virus was employed." G Stuart

PLAGUE

CHEN, T H. The Behavior of *Pasteurella pestis* in Glycerin and Rhamnose Mediums. *J Infect Dis* 1949, July-Aug, v 85, No 1, 97-100 [24 refs]

In a study of 53 strains of *Pasteurella pestis* from the collection in the University of California the author found that three were "glycerin positive", producing acid in culture media containing glycerol.

From an analytical survey of the literature it is concluded that the glycerol-positive and glycerol-negative strains seldom occur together in the same region.

All but one of the many strains hitherto recorded from Manchuria, Mongolia, South-East Russia, Turkestan, and South Russia have been glycerol-positive, whereas nearly all the strains from other parts of the world have been glycerol-negative.

The author admits that further studies are needed before the preponderance of this distribution can be gauged. He also mentions that some workers have found that glycerol-positive strains have become glycerol-negative after long storage or after subcultivation.

PAZDROKOWSKI, T. Rats from the Ports of Gdynia and Gdansk (Poland).
Bull. U. S. Marine & Trop. Med., Med. Acad. Gdansk, Po. 1, 1949, v. 1
No. 1, 13-16.

In a survey of 874 rats from the port of Gdynia and 786 from the port of Gdansk, it was found that nearly 90 per cent were *Rattus norvegicus* and the rest were *R. albus*.

Among 92 rats taken on ships in the harbours only five were *R. norvegicus*. These surveys were made up to October 1, 1947.

In the port of Gdynia a previous survey made in 1934 gave quite different results: 50.6 per cent of the rats were *R. norvegicus* and 49.4 were *R. albus*.

The explanation of the difference is believed to be the wartime cessation of seaborne traffic and the resulting interruption of the influx of *R. albus* from ships.

LIVA, V. H. Plague among Wild Rodents in Rio Arriba County, New Mexico.
Amer. J. Trop. Med., 1949, July, No. 4, 473-477, 1 fig.

The author describes a thorough investigation made over two years, May and August 1949, into the presence of plague infection in Rio Arriba County in New Mexico, on the Colorado border.

The County is 5,871 square miles in area, the population is 23,336. In 1940 no evidence of infection was found among 470 animals from 25 different areas of the County. In 1943 there were many deaths among the wild animals of one area, and since that time practically all the animals have been reported from one time and disappearing temporarily or permanently from all other areas, presumably as the result of plague infection.

In the present study 371 rodents belonging to 20 species and 72 other animals were trapped or shot. Thelastosporeidites were collected and examined.

The only animal found infected was the prairie dog (*Citellus pygmaeus*), of which 94 were examined. Plague infection was stated from 15 of 14 fleas collected from 11 of the animals and from the tissues of five others.

From 12 marmots (*Marmota flaviventris*) only two strains of bacteria were isolated. One of the strains was from a pool of blood collected from a dead animal; the other was from a pool of blood collected from a living animal. From the latter group 1 animal (8 fleas) and 6 ticks were isolated but were found free from infection.

No cases of human plague have been known to occur in this area. The only human infection reported was a small fever of the form of dengue.

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

GELIN, G Retentissement cardio-vasculaire de l'amibiase chronique A propos de 80 observations recueillies en un an en Oranie [Cardio-vascular Complications in Chronic Amoebiasis 80 Cases collected in Oran in a Year] *Bull et Mém Soc Méd Hôpit de Paris* 1949 Nos 21/22, 788-94

HERNÁNDEZ VARGAS, C R Nuevo tratamiento de la amibiase intestinal [A New Treatment of Intestinal Amoebiasis] *Rev Facul de Med Bogota* 1949, Mar, v 17, No 9, 415-55 [16 refs]

The "new treatment" here described is, in essence, a combination of drugs which have been tried singly with varying success. The author has divided his account into five chapters of which the first gives some data on the prevalence of infection by *Entamoeba histolytica* in Columbia between 1916 and 1943, and the second consists of remarks on ipecacuanha, emetine, E B I, arsenicals such as treparsol and stovarsol, and on yatren, vioform and diodoquin, culled from the literature and containing nothing new. Chapter III explains the rationale of the suggested treatment—the simultaneous administration of emetine, penicillin and sulphaguanidine. Originally, by what is called the Hargreaves method, in 1944, emetine hydrochloride was injected in a daily dose of 0.06 gm for seven days, then 0.4 gm till "the total in centigrammes was equivalent to the patient's weight in kilogrammes". If a second course was needed 45 days were allowed to elapse after the first. At the same time as the emetine there were injected 200,000 units of penicillin every day, divided into eight doses, at intervals of three hours for one week, and sulphaguanidine was given, 4 gm four times a day (16 gm daily) for a week, totalling 112 gm.

In 1947 this method was modified and the course consisted of three phases: i. Of six days during which there were given daily injections of 0.06 gm emetine, together with one million units of penicillin in doses of 33,000 units every three hours and 20 gm of sulphaguanidine or sulphamethazine, 1 gm every four hours. ii. Of 12 days, emetine bismuth iodide 0.12 gm (2 grains) every night and a retention enema of 4-6 oz of chiniofon, 1-4 per cent daily. iii. Of 20 days, diodoquin 0.63 gm three times a day. The patient may be up and about during the third phase, but in hospital for the first two. The author has slightly modified this procedure as follows. Days 1 to 6 emetine hydrochloride, 0.06 gm daily, preceded by injection of some cardiac tonic such as sparteine, penicillin, 33,000 units every three hours to a total of 1,000,000 units, and sulphadiazine 1 gm every four hours to a total of 20 gm. Days 7 to 18 Daily retention enema of 4 oz of chiniofon, 2-4 per cent, after a wash out with 2 per cent sodium bicarbonate, bismuth subnitrate in capsules containing 0.5-1 gm, three a day. Days 19 to 36 Five tablets of diodoquin daily, two in the morning, one at mid-day and two at night, each containing 210 mgm.

The advantages claimed for this procedure are that the dose of emetine is reduced to a minimum compatible with efficiency and toxic symptoms are avoided, the associated drugs act on the intestinal bacterial flora, the iodides act on the cystic forms of the entamoeba and the bismuth counteracts the possible diarrhoeic action of the chiniofon.

Twenty cases are detailed, 16 males, four females, whose ages ranged between 17 and 60 years. Generally, symptoms showed improvement in six days. Sixteen patients were cured, in four there was no benefit, at least no lasting benefit, but two of these suffered also from tuberculosis and two had a heavy infestation with hookworm.

H Harold Scott

abandoned in the United States in favour of the former. There are many cases of chronic amoebiasis among US war veterans, some of whom have been subjected to unsuccessful treatment, others of whom have not. This fact and the general dissatisfaction with, and lack of agreement on, the current therapy of amoebiasis have encouraged the authors to search for a more effective amoebicide than any so far available.

The thioarsenite C C 906 (p-carbamidophenyl arsenous acid) (or carbarsone oxide) was the most effective amoebicide against *E. histolytica* discovered by laboratory test, although more than ten times as active as carbarsone (p-carbamidophenyl arsenic acid) it proved much more toxic, probably because the valence of the arsenic was three rather than five. Substitution of -SH groups for oxygen reduces the toxicity of arsenicals, and two such derivatives of carbarsone oxide, C C 914 (p-carbamidophenyl-bis (carboxymethylmercapto) arsine) and C C 1037 (p-carbamidophenyl-bis (2-carboxyphenylmercapto) arsine), proved less toxic to the tissues in amoebiasis of monkeys while largely retaining their amoebicidal activity *in vitro* and *in vivo*. These two compounds were subjected to clinical trial, in Tennessee and in Costa Rica, on 100 patients suffering from a variety of protozoal and helminthic infections. Of 82 patients (77 infected with *E. histolytica*, two with *Dientamoeba fragilis*, and two with *Balanidium coli*), treated with one or other of these compounds, 74 were freed of their parasites, as judged by 6-12 stool examinations during the ensuing four months. Another 18 patients (two infected with *D. fragilis*, 12 with *Strongyloides stercoralis*, one with *Fasciola hepatica*, two with *Leishmania tropica*, and three with *Treponema pertenue*) were similarly treated but without benefit. The dosages employed ranged from 3.0 gm orally in ten days to 7.2 gm in 24 days, the smaller dosage was just as effective as the larger, 13 patients with acute dysentery were given 3.0 to 6.0 gm of C C 1037 in six days in retention enema. No toxic side-effects were observed other than nausea and vomiting in 12 cases, coating the pills with phenyl salicylate obviated this. The authors conclude that these two thioarsenites are therapeutically effective amoebicides in doses 1/10 to 1/5 that of carbarsone, and they can safely be given orally thrice daily for ten days in enteric-coated tablets containing 25 to 50 mgm of the drug, in severe cases of dysentery they may be given as retention enema.

DE LA GARZA BRITO, A & TREVIÑO VILLASEÑOR, A. Nota preliminar sobre la acción terapéutica de un nuevo amebicida. [Preliminary Note on a New Amoebicide] *Medicina Mexico* 1949, July 10, v 29, No 583, 261-9.

[The question immediately arises to anyone reading this article, "When does a drug cease to be new?"] The drug referred to here is Win 1011, the amoebicidal action of which was proved by HAUER in 1943 [see this *Bulletin*, 1943, v 40, 913, where it is called "Wja" throughout]. The name was given because the drug is a product of the Winthrop-Sterling Institute, Mexico. It contains approximately 37 per cent of bismuth and 15.7 per cent of pentavalent arsenic, and is put up in tablets of 0.25 gm. The authors give details of ten patients treated, one was given six tablets daily for ten days, one had four, but all the others received five daily for the ten days. Tolerance was generally good, there might be complaint of headache and a little colic or nausea, but not enough to cut short the treatment. At the end of the course, and often after four days or so only, no *Entamoeba histolytica* could be seen in the stools and proctoscopic examination was also negative.

LUIS CARRI, E. Equivalente epileptiforme por giardiasis intestinal. [Epileptiform Manifestations in Giardiasis] *Archivos Sec. Salud Pública de la Nación* Buenos Aires 1948, June, v 3, No 19, 57-60.

WHEELER I. V. & LACOURT J. Artamibosia A la Glándula tiro J. N. Chile 1949 Aug. v. 78 No. 2, 257-9 4 figs.

A child 24 months of age with kerat emulacia of both eyes was demonstrated to have a *Clonorchis* infection. He had a at the time of 1st chronic anemia and low vitamin A content in the bile. The curves for both vitamin A absorption and desaturation showed exceptionally poor absorption of these materials.

After the parasite had been eradicated, the absorption of both vitamin A and carotene became normal, the excess fat disappeared from the feces, the patient gained much weight and his anemia greatly improved."

ALLEN M. & BAKER G. *Coccidiosis humana de Intestino* (Review) in *Archivos de Medicina*. Coincident Infestation by *Isospora belli* and *Isospora belli*. *Archivos de Medicina* 1949 Sept. v. 10 No. 3, 143-5. 1 fig. 1 table. English summary (4 lines).

A woman of 74 years, employed with her husband in gardening, complained of vague abdominal pain and disturbance with weakness and diarrhea. She, her husband and five children all were harbouring hookworms and the patient herself was infected also with *Isospora belli* and *Trichuris trichiura*. A definite causal connection could not be made on account of an interperalade pykotic system. Treatment by thymol reduced both infestations. This was followed by chloroform and eucalyptus oil in castor oil, but the first dose of this caused great general disturbance so no more was given, but improvement was rapid and examination of the stool showed no more parasites. A strange fact is recorded but not explained, the Wawermann reaction tested after the first bowel from the chloroform and eucalyptus oil was strongly positive. When the third was cleared the test was again carried out but this time was completely negative.

LEPROSY

VALLE C. O novo social leprosy. Leprosy in its Social Aspect. *Revista de Medicina* Rio de Janeiro, 1949 June. 6 No. 6, 400-1.

This article is of the nature of a general talk on leprosy in Brazil, the ignorance of the masses concerning the disease, factors which influence its spread, in short, the epidemiology of leprosy in general terms. Of secret facts and speculations based on them are at the end of the paper. It is stated that according to official returns there are 70 leprosy institutions in Brazil, these include leproseries, colonies, a storm hospital, a leprosy and contain 31,823 patients. In addition to these there are many isolated their homes and others, a large one provincial parishes which would bring the total to about 90,000, this would allow only 77 for each of the 11 groups. The average number infected by each taken arbitrarily, there so that there may be said to be 63,000, but it need not be taken in the 11 or 81,000 infected or latent or potentially infective. Taking the total population as 43 millions this would give 1 in 630. As to the members of the family and social contacts in close touch are supposed to be 31 x each or a total 147,000 and these together with the 63,000 above mean that more than 500,000 persons must be considered when the problem of leprosy prophylaxis comes under discussion.

Leprosy

Vol 46, No 12]

BECHELLI, L M & ROTBERG, A Idade e lepra estudo dos fatores exposição e resistência [Age and Leprosy, a Study of the Factors of Exposure and Resistance] *Rev Brasileira Leprologia* S Paulo 1949, Mar, v 17, No 1, 31-44, 2 figs [56 refs] English summary

If we were to judge from statements in medical literature, say the authors, we would infer that childhood and early adolescence are the ages when leprosy is most often contracted, and this is explained [so far as it can be called explanation and not mere tautology] by saying that the young and immature body is more susceptible to infection. From a study of records from Hawaii, New Caledonia and Nauru Islands, and of the indigenous and immigrant population of São Paulo, they infer that the incidence, or rather the prevalence, depends not so much on age as on the degree of exposure to infection. Thus, in the islands mentioned, children and adults are about equally exposed, in São Paulo, among the indigenous population the incidence in descending order was the 4th, 3rd, 5th, 6th, 2nd, 7th and 1st decades, among the relative age [immigrants] 5th, 6th, 7th, 4th, 3rd, 2nd and 1st.

For purposes of comparison the authors show by graphs the relative age incidence of measles and conclude that "depending on an earlier or a later age of exposure and on the resistance of the individuals in contact with infectious foci, a higher incidence of the disease among children or adults will be observed"

H Harold Scott

DE FARIA, J L Valor do metodo de Faraco para coloração do bacilo de Hansen em cortes [Value of Faraco's Method for the Staining of the Hansen Bacillus in Paraffin Sections] *Rev Brasileira Leprologia* S Paulo 1949, Mar, v 17, No 1, 18-26, 2 figs on 1 pl [13 refs] English summary

Faraco's method of staining Hansen's bacillus has been regarded by some as a modification of the Ziehl-Neelsen procedure, but this is not a correct view. The principle consists in treating the section, before staining with fuchsin, with some fatty or oily substance—liquid paraffin, cod-liver oil, Singer's alcohol and xylol. The method is as follows —

Fix the tissue in 10 per cent formalin, then pass in the usual way to embedding in paraffin. Cut sections 4-6 μ in thickness, remove the paraffin with xylol and then pass through alcohols to water. Deposit Merck's liquid paraffin on the section and heat till steam rises, allow to cool, blot with filter paper till the section becomes opaque, stain with hot acid fuchsin, as by the Ziehl-Neelsen method, wash in water, then in liquid soap, pure or a little diluted; wash well in water and pass rapidly through alcohol 70 per cent, wash again in water, differentiate in 25 per cent sulphuric acid till the section is a light red on washing in water, wash in running water for at least 10 minutes, stain lightly with methylene blue so that the section appears a reddish-blue, not a pure blue, then pass through alcohol and xylol and mount in neutral balsam.

Tissue from 36 patients whose lesions showed very few bacilli were stained by the Ziehl-Neelsen and by the Faraco techniques, 10 were positive by the former, but 14 by the latter, and when organisms were seen by both the numbers were much greater by the Faraco technique. The author found also that organisms present in old lesions might have lost much of their acid-fastness and so be recognizable only with difficulty by the Ziehl-Neelsen technique, whereas this property seemed to be restored by the Faraco method.

DE SOUZA ARACIO, H. C. Estudo bacteriológico de excetos de leprosin tuberculosos em tratamento com a estreptomycina com êxito das culturas obtidas. Bacteriological Study of Sputa of Tuberculous Leprosy Patients treated with Streptomycin. *Hefila*. Rio de Janeiro 1949. Mai v 73 No. 5 755-6.

In 1941 the author recorded the results of examination of the sputa of patient suspected of being also tuberculous and obtained positive culture in nearly one in three. In the next two years he obtained an even higher proportion (43 per cent.) In the Curupaty Colony many advanced cases also tuberculous were treated with streptomycin. Sputa of some of these were cultivated on Löwenstein-Jensen medium and 11 out of 11 gave a growth after 15 days; the specimen had been kept for a week in an ice-chest and it was to be noted that this delay might have affected the growth, so fresh specimens were asked for and cultured at once. In 15 to 20 days 11 had given a growth and so had not more of the first lot. The remaining negative of the first lot continued negative. Other specimens 14 in all were cultured and 13 gave characteristic growths of *Mycobacterium tuberculosis* of the rugose type. Streptomycin had no effect on the pulmonary organisms of these patients. Three of the patients giving a growth of *Mycobacterium tuberculosis* gave also growths of chromogenic acid-alcohol fast organisms such as the author has already obtained from leprosy patients. These are to be specially studied and will be reported upon later.

BLUMENFELD, F. (Estudo do comportamento da alergia tuberculosa em doentes de leprosin após a cura. Alergia Response to BCG by the Children of Leprosy Patients.) *Rev. Brasileira de Leprosia*. S. Paulo 1949. Mar v 17 No. 1 27-30.

The author tested 164 children of leprosy patients ranging in age up to 14 years by the Mantoux test using OT 1:100, 1:100 and 1:10 regarding as negative those failing to respond to the last dilution. 70 (42.6 per cent.) proved positive 94 negative. The M. tuberculosis test was made with injection of 0.1 cc. of leprosin and the result read 71-90 days later. 81 per cent. reacted among those tuberculin positive and 87.9 per cent. those tuberculin-negative.

Eighty-four of the tuberculin-negative were given a single dose per os of 20 cgm. of BCG and a month later 82 of them were tested by the Mantoux test 1:100 and, if negative, 1:10. 11 (13.3 per cent.) were positive. When 78 of them were tested again a year later only 77 (25.5 per cent.) were positive 49 being negative.

By way of comparison 173 of the inmates of an orphanage whose ages ranged between 4 and 17 years, were similarly tested with tuberculin. 103 (59.5 per cent.) were positive, the other 70 were given BCG and 43 of these were tested for allergy to tuberculin one month and again in one year afterwards. 70.7 and 71.3 per cent. respectively were positive.

The author concludes that the children of leprosy subjects M. tuberculosis react to tuberculin in about the same proportion as a control group of non-leprosy persons, that is there is no group sensitization due to the presence of *Mycobacterium leprosy*. Further allergy can arise from BCG in children already sensitized to *Mycobacterium leprosy* is more transient than that found in the general population (as evidenced by the orphanage children). In fact allergy to leprosin presumably set up far from favoring allergy to tuberculin, it causes in the body a certain anergic action evidenced when one tests the tuberculin allergy of milk-intoxicated such as that produced by BCG.

DE AQUINO, U M Observação e discussão de um caso de lepra tuberculoide Mitsuda-negativo, reação focal despertada pela tuberculina [Observation and Discussion of a Case of Tuberculoïd Leprosy, Mitsuda-negative, Reaction brought out by Tuberculin] *Hospital* Rio de Janeiro 1949, May, v 35, No 5, 745-53, 2 figs [14 refs]

A Brazilian white man, 25 years of age, who gave no family history of leprosy but who had married a woman with the clinically diagnosed lepromatous form of the disease, presented himself with a 5-months' history of symptoms when examined, he showed maculo-erythematous, hypochromic and achromic patches with clear edges but covering fairly large areas on the trunk and limbs, and anaesthesia to heat and pain over the areas supplied by the cubital, popliteal and peroneal nerves, the hands were amyotrophic (*main-en-griffe*)

Bacteriologically, the nasal mucosa and skin from various sites were negative, the early Fernandez and the late Mitsuda reactions were both negative. An intradermal Mantoux reaction was then tested with tuberculin 1:10,000 and in 24 hours there was a local infiltration 25 mm in diameter and a general reaction in all the leprides, especially marked in those of the forehead, and there was systemic disturbance, in 48 hours the local erythematous infiltration had reached 30 mm, after this the general disturbance began to improve, the local reaction was disappearing after 4 days, but the "lesion reactions" have persisted "up to the present" [interval not stated] *H Harold Scott*

ZAVALLIA, A U Ação das diamino-difenil-sulfonas sobre as complicações oculares da lepra [Action of Promin on the Eye Lesions of Leprosy] *Rev Brasileira Leprologia* S Paulo 1949, Mar, v 17, No 1, 5-17

Much useful information may be gained even from negative results of an experiment. In view of the favourable reports on the use of Promin in leprosy the author has tested this compound in 25 leprosy patients, whom he divided into 4 groups. Each patient received 100 intravenous injections over a period of 4 months, the injection was given daily, except on Sundays, the first dose being 5 cc or 2 gm of the drug, and the subsequent doses 12.5 cc (5 gm), with a 30 days' rest after the course.

Group I, 5 patients, suffering from the lepromatous form in an early stage, or the indeterminate type, but without any ocular lesions. Each patient received about 1,200 gm (stated as $1,184 \pm 285$) during a period of 14 months or so, average 14.20 ± 2.49 months. In none of them did any eye complications occur, one improved clinically, but not in any other way, i.e., bacteriologically no change could be detected. Group II, 7 patients, with moderately advanced lepromatous stage (L_2) and slight ocular lesions, some infiltration of the cornea and thickening of the circum-corneal nerves. These received $1,207 \pm 267.5$ gm of Promin over a period of 13.86 ± 3.08 months. Three showed a distinct improvement in the eye condition, disappearance of thickening of the nerve-ring and partial resorption of the infiltration, in two there was no change and in the other two a nodular iritis and extension of the lesion to the anterior part of the uvea. Group III, 5 patients, in a more advanced stage of L_2 and more severe eye lesions with nodular iritis. They received $1,160 \pm 147.1$ gm of Promin during a period of 11.80 ± 2.86 months. Of these, in one the condition remained stationary, in the others the military nodules increased in number and, in short, they became worse. Group IV, 8 patients, with a more advanced lepromatous form (L_3), and more severe eye complications, keratitis, nodules in the iris and diffuse irido-cyclitis. The ranges of dose here seem to have been greater, for the author states that they received an average dose of only 934 ± 317.2 gm, because the degrees of tolerance were so varied, and the

average duration of treatment was 17 ± 4.04 months. In 6 of the 8 the ocular lesions became definitely worse the nodules increased and the iridocyclitis extended. In one the condition remained unchanged and in one only was improvement observed both in the interstitial keratitis and the acute iridocyclitis present. It can only conclude therefore that Proton will not arrest or delay the development of the slow and progressing ocular lesions of leprosy.

GUADAGUAYO M. LA cirugía en la lepra. [Surgery in Leprosy] *Archivos Soc. Salud Pública de la V. n. Nuevo Alcaz. 1945, Aug. 4* No. 2, 139-51. 11 refs. (17 ref.)

GUADAGUAYO M. A. El tratamiento quirúrgico de las neuritis hipertroóficas de la lepra. [Surgical Treatment of Hypertrophic Neuritis in Leprosy] *Archivos Soc. Salud Pública de la V. n. Nuevo Alcaz. 1947 Feb. 1* No. 3, 4, 13, 7 figs. 10 refs.

Enlargement of certain nerves notably the cubital, the external popliteal and the median is commonly observed in leprosy. In this enlargement there are three stages of evolution. The first, in which the acuteness of the pain leads to the limb being kept semiflexed and as immobile as possible because movement increases the pain. In addition to the pain there is hyperaesthesia with tortication, weakness and slowness of muscular movement. The second in which the pain is on the whole less intense and less persistent, but occurs in exacerbations and signs of wasting of muscles appear. In the third, the atrophy is marked, with functional incapacity, but no pain.

Surgical intervention is useful in the first two stages, not in the third. Operation consists in freeing the swollen nerve from its sheath and the fibrous epineurium and endoneurium. The stages are well shown in a series of photographs. The results are reported of 77 patients thus treated. In 7 the pain was completely relieved, in 30 the nerve function improved, in 20 there was no change in this respect. Of 54 in whom the cubital nerve was thus dealt with 21 obtained improved function with disappearance of the pain, 24 lost their pain but functionally there was no change, in 5 the pain returned. Of 10 with external popliteal involvement 7 had no more pain and the limb improved, in the other 3 function was unaffected although the pain disappeared. Four had median nerve involvement, all lost their pain, but in two only did the function improve, it remained unaffected in the other two.

HELMINTHIASIS

LOUGHEIX E. H. & SPRUE N. H. Diagnosis of Helminthiasis. *J. Amer. Med. Ass. 1949 Apr. 9* 140 No. 15, 107-100. Refs. in footnotes.

Stoll estimates that there are 700 million tapeworm, 149 million hookworm and 2,000 million roundworm infections in the world this month, 1947, or 44.6%. A not insignificant percentage of these is encountered in the United States and Canada. Since the return of immigration a number of foreign species have been introduced into these countries. Of 15 now from the Pacific area were infected with tapeworms, hookworms and many had schistosomiasis.

For examination of faeces the authors describe a concrete box method (CEM). To 40 ml. of faeces add 4 ml. of 10% indigo carmine laboratory alcohol (flocyt) and 10 ml. of 10% formalin. Mix and allow to stand.

and kept overnight, and shaken again. 1.5 ml is now placed in a 15 ml pointed centrifuge tube, to which 3.5 ml isotonic saline, 5 ml ether and 2 drops of xylene are added. This is shaken well and centrifuged at 2,000 revolutions per minute for 1½ minutes. The debris is wiped away and the supernatant fluid poured off. One or two drops of saline are added to the deposit which is placed on a slide by means of a pipette and examined. The whole sediment represents 0.1 gramme of faeces.

The authors propose a "diagnostic plan" which consists of a careful geographical history, naked-eye inspection of faeces passed without a cathartic, followed by a direct watery smear of a selected portion, a CEX concentration as described above, a cellulose tape and smear for *Enterobius*, charcoal culture of the stool, proctoscopy, and rectal biopsy.

In discussing the differential diagnosis they emphasize that each worm infection may mimic many serious organic maladies. They issue a warning, however, that the finding of an helminthic infection does not exclude co-existing organic disease.

MARILL, F G, HOFMAN, M & BERTOZZI, P. Le foyer de bilharziose urinaire de Fondouk (Algérie) [The Focus of Urinary Schistosomiasis in Fondouk (Algeria)] *Arch Inst Pasteur d'Algérie* 1949, June, v 27, No 2, 110-27, 1 map & 8 figs on 4 pls.

The first focus of *Schistosoma haematobium* infection in Algeria was found in 1939 [this *Bulletin*, 1940, v 37, 150, 483], the existence of a second at Fondouk has now come to light. This evidence of spread of the range of the parasite in Algeria is the more significant now that extensive irrigation schemes are being undertaken. The water courses, reservoirs and irrigation distribution, and the climatic and geological conditions in the Fondouk area are described in detail.

Investigation has revealed 67 cases of urinary bilharziasis in Fondouk, two of the sufferers were Europeans, the rest Mussulmans, all were males ranging in age from 8 to 50 years, the highest incidence of infection being in the younger patients. All the patients were infected by bathing in the river Hamiz, which has been dammed to form an irrigation reservoir, and it would appear that the infestations date from the summer of 1946. Specimens of *Physa acuta*, *Bulinus contortus* [truncatus], and *Planorbis metidjensis* have been found in the area.

The possibilities for spread of the infection obviously are great, and measures are suggested to limit it.

MEESER, C V, ROSS, W F & BLAIR, D M. Further Observations on the Macroscopic Diagnosis of Urinary Schistosomiasis. *J Trop Med & Hyg* 1948, Mar, v 51, No 3, 54-9, 3 figs.

In this paper the authors describe in detail their reconstruction and use of the miracidiascope with its optical arrangement, originally designed by GORMAN and the present authors [this *Bulletin*, 1948, v 45, 258]. They discuss its use in the diagnosis of urinary schistosomiasis.

The miracidiascope consists of a specially constructed wooden rack painted dull black to hold centrifuge tubes and a hand lens 1 in in diameter and of 2½ in focal length, to view the miracidia swimming about in water.

The value of the instrument is two-fold.

(1) The procedure is relatively simple and an opinion as to the presence of the disease can be given in an outstation clinic or during a routine school inspection without costly apparatus or specialized training.

a membrane was formed around those cercariae which had been placed in immune serum, but was absent from those immersed in control serum, a phenomenon referred to by the authors as the "*Cercarienhiillen Reaktion*" or CHR test. The subject was reinvestigated in 1947, and it is with the results then obtained that the present paper is concerned. The technique of carrying out the CHR test is very simple—it essentially consists in mixing together on a slide a drop of the serum to be tested and a drop of water containing a concentration of living cercariae, usually 30–50. The reaction was shown to be non-specific, but it was found that *S. mansoni* cercariae tended to give the strongest reaction when tested against the sera of mammalian hosts, regardless of whether these were infected with *S. japonicum*, *S. haematobium* or *S. mansoni*.

A well-marked +++ positive reaction is characterized by the appearance, within 1–2 minutes of immersion, of a narrow, clear zone, which is in reality a homogeneous membrane, surrounding the cercariae. This membrane rapidly increases in distinctness and depth, to 3μ or wider, while the previously smooth edge becomes contoured. In less well-marked (++ and +) reactions, the time taken for the reaction to develop is longer and the membrane produced is thinner and less distinct in outline. Having recorded by this means the reactions given by the sera obtained from a large number of infected animals—monkeys, dogs, cats, mice and rabbits—and from a few human infections, the authors repeated the observations using various dilutions of the serum, and ascertained the highest dilution, the end point, at which the reaction was observable. The combined results of these two investigations are given as follows. A strong +++ positive reaction is characterized by the formation of a membrane not less than 3μ in depth, and the highest dilution of serum in which a reaction can be noted is 1/80 to 1/160. A moderate ++ positive reaction is characterized by the production of a membrane 2– 3μ in depth, and an end-point in the serum dilution of 1/40. Distinct but less well-marked reactions are classed as weak (+) positive reactions. A drop of dried blood may be substituted for the serum; this technique sometimes gave results similar to those obtained with the serum, but on some occasions the result was negative when the serum reaction was positive, and for this reason the method was abandoned as unsatisfactory. It was observed that inactivated serum gave the same results as normal serum, and that cercariae killed by heating to 56°C gave a positive reaction, whereas those heated to 100°C did not do so.

With the use of the CHR technique already described a large series of infected and uninfected animals was examined. The results obtained are recorded in the paper in detail, but they may be summarized by saying that with the exception of mice, all animals infected with any one of the three species of human schistosomes and found negative before infection, gave a positive reaction at an early stage after the infection was established. On the other hand, among 3 monkeys, 7 dogs, 13 rabbits and 20 mice found free from all forms of trematode infections, one rabbit and one dog gave a positive CHR reaction.

As regards human infections, the sera of seven patients excreting Schistosome eggs, or having excreted them one to five months previously, all gave a positive CHR. The sera of five patients, who had previously been infected but who for the past five years had been symptomless and were no longer excreting eggs, were negative. A control test carried out on 157 residents of Hamburg in whom the possibility of schistosome infection could be dismissed gave no positive results except in one instance where the serum gave a feeble positive reaction on the first examination and was negative on subsequent examinations [This case is omitted from the authors' summary].

(7) It can be employed in the determination of viability of ova. There are certain microscopic criteria of viability but this macroscopic method may be used in addition for the purpose.

Many useful practical points in the preparation of specimens are discussed these should be read in the original.

The terminal portion of the urine vessel is collected and allowed to stand for approximately 30 minutes after which the upper part is decanted, leaving sufficient behind to fill a centrifuge tube. This is centrifuged at low speed and the liquid gently drained off. Five ml. of water (either filtered and boiled pond or rain water) are added to the deposit. The tube is then inserted in one of the holes provided in the rack. Hatching is usually complete within 30 minutes but may be delayed up to 40 minutes. If viable ova are present in the urinary specimen these hatch and the miracidia can be seen through the lens swimming around actively in the water.

The authors conducted comparative trials with the microdissection and the already established microscopic technique. Of 173 specimens of urine examined, 294 (23 per cent) were positive for ova microscopically and 243 (14 per cent) by the microdissection. In 11 (16 per cent) the infection was recognized by both methods. Diagnosis was established on miracidial hatching alone but not microscopically in 35 cases whereas in 84 it was made microscopically but no miracidia were seen to hatch. In 33 of these 84 cases the ova were non-viable. The paper is illustrated by two photographs and one figure of the microdissection. *H. Garland*

GUHBERT R. Die Struktur der Körperoberfläche von *Filicaria murina* (Lamborn 1907) (Structure of the Body-Covering of "murina") *Zisch f. Tropenmed u. Parasit.* Stuttgart 1949 v. 1 N. 1 105-114 4 figs.

Looms a classical work on the anatomy of *Filicaria harnaldi* was published in 1915. It was not until 1937 however that a distinction between *F. harnaldi* (Loom) and *F. murina* was recognized and there appears to be little doubt that Loom's description of the body-covering in the genus *Filicaria* was founded on a study of material containing a mixture of both these species. The author of the present paper has had the opportunity of studying material obtained from mice infected with *F. murina* and killed after treatment with "Nirvan" (He makes no reference to the possibility that the drug may have altered the normal appearance of the worms). The observations recorded are confined to this species and the results obtained from the investigation have confirmed and amplified Loom's findings particularly as regard the thick layer of the pores on the overlapping edges of the proscaphites and as that this structure remains closed without muscular effort on the part of the male.

The author's observations are limited to the main part of the cuticulously carinated and vacuolated integument as unpaired, ciliated diagrammatic drawings of the morphology and anatomical distribution of the various types of pores occur on the body-covering of both sexes of *F. murina*. *R. M. Gordon*

VOGLT H. & MEYER C. W. Hüllbildung bei *Filicaria* (Loom) im Serum *Filicaria-infizierter Tiere und deren Membran-Formierung in Schistosoma Cercariae placed in Serum of Animals and Man infected with Schistosomes.* *Zent. f. Bakt. Abt. I Orig.* 1949 143 91 105 4 figs. 17 ref.

In 1940 the author investigated the survival time of *Filicaria murina* cercariae placed in serum obtained from immune and non-immune animals and believed that

complexity of the present system has resulted in part at any rate from too little attention having been paid to the constantly changing morphology which accompanies growth in molluscs, and which is further influenced by food supply and environment, he points out that these difficulties do not beset the entomologist who is concerned with creatures which, for the main part, undergo but little change after they have reached the adult stage. The author might well have added that the entomologist bases his classification on the complete specimen whereas the malacologist is often asked to base his classification on the shell only. AUBOTT (this *Bulletin*, 1948, v. 45, 1096).

During recent years the author has made a special study of the *Platiorbidae* of the Belgian Congo, not only has he studied the collections of other workers in various parts of the world but he has carried out extensive surveys in the field and has maintained and bred many species of the schistosomiasis vectors under artificial conditions. As a result of these studies, and with the approval and co-operation of Dr. J. Bequaert, he suggests a simplified classification and considers that the *Platiorbinae* of the Belgian Congo should be classified and named as follows:—

- 1 *Biomphalaria alexandrina* var *pfeifferi* (Krüss 1948)
- 2 *Biomphalaria alexandrina* var *tan-ganyensis* (F. A. Smith 1881)
- 3 *Biomphalaria alexandrina* var *stansleyi* (E. A. Smith 1888)
- 4 *Biomphalaria alexandrina* var *clau-on-phala* (von Martens 1879)

For doctor, veterinary surgeons and others who are not familiar with the terminology of the malacologist the classification can be simplified and modified as follows:—

- 1 *Pf. pleifferi* shell of moderate size, more or less globulose and without a keel. Occurs in streams, ponds and marshes.
- 2 *Pf. tanagericensis* large flat shells without a keel. Occurs in Lake Tanagerivaka.
- 3 *Pf. starleyi* shell of moderate size, globulose, with a keel on one side only. Occurs in Lakes Kivu, Edward and Albert.
- 4 *Pf. chevronophilus* shells higher than *Pf. starleyi*, with a prominent keel on both surfaces. Occurs in the same three lakes as 3.

The reason for this classification which the author admits may err on the side of over-simplification are set out fully in the text and should be consulted in the original by those who are interested. R. M. Gordon

Summary: 1. Note préliminaire sur le rôle de la bion par les notes et variétés des Plurales en plus resp de l'Afrique éthiopienne dans la transmission de *Schistosoma* (P. Harwood) intestinales. Preliminary Note on the Role of All Varieties of *Plurales* in the Belgian Congo in the Transmission of *Schistosoma* (P. Harwood) intestinales. Ann. Soc. Bel. et Méd. Trop. 1949 Mar 31. 29 No 1: 67-71.

[illegible]

The authors present evidence to prove that the membrane formed around the cercaria is not derived from any outpouring of fluid from the cephalic gland, the latter resulting in a granular mass, sometimes visible inside the clear membrane characteristic of the CHR reaction. They cannot state how the membrane originates, but they postulate that it arises from certain constituents occurring in the serum of animals infected with schistosomes coming into contact with fluid diffusing through the cuticle of the cercariae. The authors were at first of the opinion that the membrane they described might affect the ability of the cercariae to develop in the final host, and that it might be responsible for the immunity to superinfection which was observed in a proportion of the animals giving the reaction. Further observations and experiments, which are fully described, have caused them to alter this opinion, and they now consider that the membrane is in no way responsible for acquired immunity in schistosomes. A inference has already been made to the fact that the CHR reaction cannot be used to distinguish the species of a histosome involved, and the authors carried out a further series of experiments to try to determine it more clearly. No reaction was obtained with the sera of animals and persons infected with various species of tapeworm, nor with the sera of two rats infected with *Opisthorchis schistosomus*. On the other hand the sera of cattle infected with *Fasciola hepatica* gave a positive CHR when tested against schistosome cercariae. This lack of specificity is a disadvantage, but the authors consider that the results so far obtained by them suggest that the test might prove of value in diagnosing human infections, and urge that it should be investigated further.

The paper adds considerably to our knowledge of the serology of trematode infections and should stimulate further investigations along the lines suggested by the authors. R. M. Gordon

SCHWETZ, J. Sur une nouvelle classification des Plasmodes du Congo Belge (Resp. de l'Afrique éthiopienne. A New Classification of Plasmodia in the Belgian Congo.) Ann. Soc. Belg. de Méd. Trop. 1940 Mar 31 v. 20 No. 1 37-44 20 figs. no pl.

The author points out the impossibility of an entomologist studying the epidemiology of malaria or tripanosomiasis without a corresponding knowledge of their vectors and that similar knowledge of at least certain groups of molluscs is necessary when investigating the epidemiology of schistosomes. When the malariologist wishes to determine the species of any anopheline with which he is concerned, he follows the well recognized rules for identification which have been prepared by expert entomologists and is still in doubt, he can rely on the opinion of a recognized authority, while similar facilities are available to the research worker studying the tsetse in tripanosomiasis. Professor Schwetz points out that modern malacology, in contrast to the modestly included as himself, are in no such fortunate position, not only as the tables of classification neither clear-cut nor well recognized, but the experts may differ amongst themselves regarding the classification of a particular specimen or group of specimens. In support of this latter statement the author remarks that having encountered difficulty in making a differential diagnosis between certain specimens he wrote the opinion of two malacologists.

La difficulté de les identifier. Pl. le nom d'espèce et il est alors d'après l'auteur.

Professor Schwetz writes that it will become the custom in a particular science to criticize the specialist, but most workers will agree with him now that the present system of classification of snail vectors is much too artificial and that a look for a revised and simplified classification is considered as the solution.

winter, it migrates to the land, where it lives in small cavities between grass roots and stones. Unlike the other snail hosts of the schistosomes, *O. hupensis* does not breed throughout the year, but only during spring and early summer, in addition, its eggs are laid singly, not in masses, each egg being enclosed in a covering of fine mineral slime. This covering acts not only as a mechanical protection, but it also forms an efficient camouflage, hence, although it was certain that the eggs were being laid in the aquaria, for young snails were appearing regularly, it was only after two years of breeding in the aquaria that the eggs were discovered. It would appear that this fine mineral slime is derived from a clay occurring in the normal habitat and that it is essential for oviposition. Without such clay, the snails will not readily breed in artificial aquaria, and under natural conditions in China the snail disappears, as does schistosomiasis, when one changes from heavy clay ground to sand or gravel. The young snails hatch from the eggs within a fortnight and, under favourable conditions, they develop very rapidly, some becoming full-grown within three months of hatching. The length of life of *O. hupensis* was not observed, it is probably similar to that of *O. nosophora* which is stated to live for five years or possibly longer.

O. hupensis is easily infected with the miracidia of *S. japonicum*, the rates of infection in seven series of experiments lay between 23.6 and 80 per cent. It tolerates infection well, and it may continue to shed cercariae for as long as a year. An interesting observation recorded in this part of the work is that *O. hupensis* infected with a single miracidium did not supply fewer cercariae than did those which had been exposed to many cercariae, probably because the digestive gland of the snail only offers sufficient food for the development of a limited number of sporocysts. Dogs, usually sheep dogs, were found to be the most satisfactory final hosts and in order to ensure that both sexes are represented among the adult schistosomes developing in these animals it is advisable to use cercariae from a number of snails, eight to eleven is the number recommended.

This paper contains exact instructions, often illustrated with clear diagrams concerning the maintenance of *O. hupensis* and the methods for its infection and it will prove invaluable to anyone endeavouring to maintain a strain of *S. japonicum* under laboratory conditions.

R M Gordon

SÉDALLIAN, P, MARAL R & PERRIN A. Epidémie familiale de distomatose à 'Fasciola hepatica' [A Familial Epidemic of Distosomiasis due to *Fasciola hepatica*] *Bull et Mém Soc Méd Hôpit de Paris* 1949 Nos 9/10, 327-33.

The authors are encouraged to report this familial outbreak of distosomiasis due to *Fasciola hepatica* by the comparative rarity of human infection with this worm. The aetiology was classical in that the patients had been eating watercress from a field in which infected cattle were kept. Women and children only were affected. All were treated by glucantime (antimonate of N-methyl-glucamine), with good results, but no claim is made that this drug is better than other anthelmintics, many of which are effective on account of the weak hold that this infection has in man.

The five cases are reported in detail. The onset and symptomatology were very similar in all the cases. It was usually gradual with malaise, shivering, periodically fever, usually low, and a non-productive cough. In every case there was epigastric pain at the onset or later.

There was albumin, usually a trace only, in four of the five cases either before or after treatment had been started, the amount increased during

COSTA R. MEXERRE H & MAGALHES A Jr. Faqueirosidade causada e perniciosa. Lesões hepáticas de robôes infectados e subcutâneas a tratamento pelo tartarato de sódio e antimonita. (Experimental Schistosomiasis murina. Hepatic Lesions caused in Infected Calomys treated with Sodium Antimony Tartrate). *Rev. Brasileira Med. Rio de Janeiro* 1943 June v 6 No 6 378-83 1st fig. English summary

For their experiments the authors infected 20 (7-4) guinea pigs with cercariae of *S. murina*. 8 were given Citibetin (sodium antimony tartrate) orally muscularly in doses ranging between 0.08 and 0.7 mgm. per gm. body weight i.e. 5-20 8 mgm. average dose and totals of 45 to 75 mgm. Sixteen were given the drug intraperitoneally in physiological saline and some of them received a second course after an interval of 20 days. Four animals died after treatment the others were killed at different intervals and their livers were fixed in 10 per cent. formalin for histological examination. Five others were not fed but left untreated as controls and killed at intervals between 49 and 105 days after infection.

The tissue changes are described and depicted in a series of plates for the macroscopical changes and photomicrographs for the histological. It was found that the worms were killed by the drug and the presence of the dead worms gave rise to nodules accompanied in places by necrosis of the tissue. Within the vessels an embolus was set up which acted as a barrier to the penetration of the decaying nutrition products. If however the worm had broken through the vessel wall to the parenchyma of the organ it caused its tissue to necrose. The fibrosis resulting from the necrotic focus if it reached the surface of the liver would by contraction produce a granular appearance of the surface. This is well shown in two of the figures. // *Howe & Co.*

VOGLI H. Letztgenige Untersuchungen über die Wirkung von Infektionsversuchen mit *Rikettsia japonica*. Maintenance of the animal & prevention and Experimental Infection of it with *R. japonica*. Reprinted from *Ztschr. f. Parasitenk.* 1943 11 70-81 8 figs. 10 p.

For a laboratory investigation of any one of the three forms of self-inoculation occurring in man it is necessary to have continued breeding of the small host. In the case of *S. murina* the author has maintained a strain of *Anthraxus* guinea for more than sixteen years and a strain of *Calomys* for several years and has found that both these species are easy to infect and give a plentiful supply of cercariae to his small host infection in the final host. In the case of *S. haematophila* the author has maintained a strain of *PA. typhus* guinea originally imported from West Africa but although his experiment of the parasite has taken place in the past he has a personal difficulty in obtaining a strain of *S. haematophila* with the results of cercariae not coming out more than three worms in Europe he has had to maintain a particular strain of *S. haematophila* in the form of a small host. On the other hand the author has found no difficulty in maintaining *S. japonica* in the form of a small host. The author has a personal difficulty in obtaining a strain of *S. japonica* which he imported from Japan but he has found that the technique has been to find all breeding of the small host in past years difficult but Vogel has found that the workers have not been successful and in order to help them he describes a method for the maintenance of infecting the small host in the form of a small host.

(1) *Howe & Co.* what kind of animal is the small host? (2) *Howe & Co.* what kind of animal is the small host? (3) *Howe & Co.* what kind of animal is the small host?

winter, it migrates to the land, where it lives in small cavities between grass roots and stones. Unlike the other snail hosts of the schistosomes, *O. lupensis* does not breed throughout the year, but only during spring and early summer, in addition, its eggs are laid singly, not in masses, each egg being enclosed in a covering of fine mineral slime. This covering acts not only as a mechanical protection, but it also forms an efficient camouflage, hence, although it was certain that the eggs were being laid in the aquaria, for young snails were appearing regularly, it was only after two years of breeding in the aquaria that the eggs were discovered. It would appear that this fine mineral slime is derived from a clay occurring in the normal habitat and that it is essential for oviposition. Without such clay, the snails will not readily breed in artificial aquaria, and under natural conditions in China the snail disappears, as does schistosomiasis, when one changes from heavy clay ground to sand or gravel. The young snails hatch from the eggs within a fortnight and, under favourable conditions, they develop very rapidly, some becoming full-grown within three months of hatching. The length of life of *O. lupensis* was not observed, it is probably similar to that of *O. nosophora*, which is stated to live for five years or possibly longer.

O. lupensis is easily infected with the miracidia of *S. japonicum*, the rates of infection in seven series of experiments lay between 23.6 and 80 per cent. It tolerates infection well, and it may continue to shed cercariae for as long as a year. An interesting observation recorded in this part of the work is that *O. lupensis* infected with a single miracidium did not supply fewer cercariae than did those which had been exposed to many cercariae, probably because the digestive gland of the snail only offers sufficient food for the development of a limited number of sporocysts. Dogs, usually sheep dogs, were found to be the most satisfactory final hosts, and in order to ensure that both sexes are represented among the adult schistosomes developing in these animals, it is advisable to use cercariae from a number of snails, eight to eleven is the number recommended.

This paper contains exact instructions, often illustrated with clear diagrams, concerning the maintenance of *O. lupensis* and the methods for its infection, and it will prove invaluable to anyone endeavouring to maintain a strain of *S. japonicum* under laboratory conditions.

SÉDALLIAN, P, MARAL, R & PERRIN A. Epidémie familiale de distomatose à "*Fasciola hepatica*" [A Familial Epidemic of Distosomiasis due to *Fasciola hepatica*] *Bull et Mém Soc Méd Hôpit de Paris* 1949, Nos 9/10, 327-33.

The authors are encouraged to report this familial outbreak of distosomiasis due to *Fasciola hepatica* by the comparative rarity of human infection with this worm. The aetiology was classical in that the patients had been eating watercress from a field in which infected cattle were kept. Women and children only were affected. All were treated by glucantime (antimonate of N-methyl-glucamine), with good results, but no claim is made that this drug is better than other anthelmintics many of which are effective on account of the weak hold that this infection has in man.

The five cases are reported in detail. The onset and symptomatology were very similar in all the cases, it was usually gradual with malaise, shivering, periodically fever, usually low, and a non-productive cough. In every case there was epigastric pain at the onset or later.

There was albumin, usually a trace only, in four of the five cases either before or after treatment had been started, the amount increased during

treatment in two cases. The blood showed a slight degree of anaemia—3.6, 3.9 and 4.4 millions of red cells per cmm. and an eosinophilia of 33, 1, 43 per cent except in the case of the elderly woman who died.

Ova of *Fasciola hepatica* were found in only two of the six, in one after treatment had been commenced, both in faeces and in bile obtained by duodenal intubation.

Treatment was by intramuscular injection of glaucantime daily for 10 days in doses of 4.5 grammes for the woman weighing 53 kg. and 3 grammes daily for ten days for the other children and the elderly woman, and 1.5 grammes for the child 1 eight years. There was usually a febrile reaction, in four cases there was a complete clinical cure but in one of these there was a complicating bacterial binary infection which was eventually cured by intravenous streptomycin after sulphonamides, penicillin and streptomycin had apparently failed. The fifth patient a woman of 68 died of anaemia after treatment she had previously damaged kidneys.

The authors believe that the albuminuria was due to the infection and that it was increased by the antimony preparation killing the parasites and causing an increase of circulatory toxin rather than by the direct effects of the drug itself since it never produces this effect in the treatment of brismaniasis.

The eosinophilia and the lung symptoms suggested Leffler's syndrome which has been shown to occur in distomiasis as well as in ascariasis.

HERNBERG, C. A. Roentgenological Visualization of the Fish Tapeworm, *Diphyllobothrium Latum*, in the Intestine of Man. A Preliminary Report. *Acta Med Scandinavica* 1949 Aug 15 v 135 No 2, 135-41 3 figs.

"Eight tapeworm carriers (*Diphyllobothrium Latum*) were roentgenologically examined after a barium contrast meal. In three cases parts of the worm could be visualized. In one case the roentgen picture showed the worm in the colon and in two cases in the ileum. In all the eight cases the peristalsis of the intestine was increased.

ARCHIVOS SOC. SALES PÉPULOS DE LA VALLE DE BUENOS AIRES 1949 May v 3, No 18 66-77. Realizase en Aral 1 Segundo Congreso Internacional de Hidatidosis. (Second International Congress on Hydatid Disease held at Aral, Buenos Aires.)

This article consists of notes of an international Congress held in May 1949 at Aral in Buenos Aires and devoted to the subject of hydatidosis. The account is itself an abstract and it is to be hoped that the Proceedings will be published in full in due course.

The Congress was opened by Dr. RICCALA DRO, the Minister of Health, and Dr. José M. JORGE was appointed President. At the first plenary session, Dr. F. rez FONTANA read a paper on the pathology of Hydatidosis of the Lung and Dr. ITURRIOTZ one on radiological interpretation. The second main feature for discussion was the surgery of Pulmonary Hydatidosis introduced by Dr. Iván Godó MORAN, and the treatment of the small and medium sized uncomplicated cysts and the large infected or hemorrhagic cysts for which resection is the only cure. Drs. M. SERRA and A. I. AGUIRRE spoke of Calceosol's biochemical method of injecting procaine down a hydatid antigen which is maintained throughout and suppresses all the symptoms and often actual cure.

The section of prophylaxis was in charge of Dr. Carlos HERNÁNDEZ who said that sheep were the most infected, and that the source of infection was pulmonary.

hydatid and that dogs are the most important vectors. Human beings are infested by the digestive route only. He refers to an instance where a dog ate infected meat and itself in time conveyed the disease to all the members of the family with which it lived.

At the second plenary session the main theme was the Biological Treatment of Hydatidosis, introduced by Dr IMAZ APPATHIE who also read a paper, conjointly with Dr LORENZ, on the Serodiagnosis of Hydatidosis. Several of the delegates spoke on Calcagnos biological treatment, in which there is used as antigen the hydatid fluid and triturated membrane in a series of progressive injections.

Resolutions were passed urging the authorities in the different States to class hydatidosis as an industrial disease. Matters proposed as major subjects for the next Congress were the biological treatment of the infestation and the surgery of *Echinococcus* infections of bones. H Harold Scott

BONNECARRERE, E. A. & ARDAO, R. La nefrectomia parcial en la hidatidosis renal [Partial Nephrectomy and Renal Hydatidosis] *Arch. Uruguavos de Med., Ciruj. y Especialidades* 1949, Feb., v 34, No 2, 221-30. 12 figs.

BATTELLI, C. Ricerche parassitologiche sui muridi di Asmara [Parasites of Rodents in Asmara] *Riv. di Parassit.* Rome 1949, Sept., v 10, No 3, 159-65. [16 refs.] English summary (4 lines).

Examining certain rodents in Asmara the author found the following parasites: *Entamoeba muris* (once), *Giardia muris*, *Diplocercomonas* (once), *Trypanosoma lewisi*, *Eimeria falciformis*, *Eimeria meschulzi* (once), *Bartonella muris*, *Anaplasma marginale*, *Hepatozoon muris*, *Sarcocystis muris*, *Cysticercus cellulosae* (once), *C. fasciolaris*, *Hymenolepis diminuta*, *H. nana* var. *fraterna* (once) and *Diphylllobothrium* larvae. Of these the only ones which might infect man are *Cysticercus cellulosae*, *Hymenolepis diminuta*, *H. nana* and the *Diphylllobothrium*. The value of the proportional findings is much reduced when we note that of the five species of rodent examined the total amounted only to 40, namely *R. rattus* 20, *Mus decumanus* and the white rat 6 each, and the house mouse and field mouse (*Arvicola*) 4 each. ANN. NEW YORK ACAD. SCI. 1948, May 25, v 50, Art 2, 19-170, 22 figs. [Numerous refs.] The Chemotherapy of Filariasis [ASHBURN, L. L. & others].

This symposium on the Chemotherapy of Filariasis was the result of a Conference held by the School of Biology of the New York Academy of Sciences on October 17th and 18th, 1947. Thirty-eight authors, many of them well known in this field of research, contributed 15 papers, covering all aspects of the subject, which will be welcomed by fellow-workers all over the world. The introductory paper by COGGESHALL describes the filarial organisms infecting man as belonging to the genera *Wuchereria*, *Onchocerca*, *Mansonella*, *Acanthocheilonema* and *Loa* and in addition the closely related filarial worm *Dracunculus medinensis*. The filarial parasites which occur in lower animals have played a large part in the experimental studies of this infection. The author briefly discusses the history of *W. bancrofti*, including its introduction to the United States. During the course of filarial infections, which tend to be chronic, no

marked immunity is produced and the possibilities of vaccine therapy appear to be limited. The major effort for protection has in the past been directed to the control of mosquito vectors. In spite of the high morbidity and infection the low mortality rate has made all but Public Health Authorities almost indifferent and the new sera proved that curative and effective chemotherapy remedies should prove of the greatest service in eliminating the infection.

In describing general experimental methods of studying filarial infection *Howzer* (who collaborates in two later papers) points out the importance attained in the cotton rat infected with the filarial worm *Leishmanoides*. In these investigations during recent years. Naturally infected animals were at first used but difficulties were encountered with this type of infection. Controlled infections in rats of known duration are now more fully employed in the chemotherapy studies. To a lesser extent dogs infected with *Dirofilaria immitis* have also been used in combination with microtechniques. Some correlation exists in the results obtained from studies in man, dogs, and cotton rat in spite of the different parasite genera involved. The promise of using the cotton rat has paid handsome dividends by providing a vehicle for the synthesis of new chemotherapeutic agents.

From their own experimental data and review of the literature *Ott* and *Mayer* conclude that trivalent arsenical are of value in the treatment of human and canine filariasis and that in this class of compounds the further substitution of phenylarsenoxides is warranted by results.

Brown outlines his investigations on the value of antihelmintic in filariasis. Dogs infected with *D. immitis* were first used in conjunction with radiographic techniques. Development of radiographic and exsanguine methods for the estimation of Schizonts possible to investigate the distribution of secretions of this substance in the body. In some patients intramuscular injection of antihelmintic produces a rapid and persistent diminution in the microfilariae of *H. bancrofti*. In dogs similar results were obtained but the action on the worm was not conclusively determined.

Van pointed out in *Cebu* reliable data in the results of chemotherapy treatment of filarial infection has only recently become available. This is now the first time that naturally infected with *Leishmanoides* as hosts for the evaluation of new filariocides. The chief effect was found to be against the adult worms. Human experiments were carried out in volunteers in Porto Rico in which infection with *H. bancrofti* was treated with trivalent pentavalent arsenical compounds with the inclusion of *As*. The author believes that the hazard of some drug treatments are greater than those of the infection and that safer drugs which preferentially can be administered by mouth as currently required. In his previous work *Van* was the best tolerated and most effective of the antihelmintic. There was no correlation between antihelmintic and blood microfilariae and *Van* believes that it is possible to eliminate infections of *H. bancrofti* by means of treatment with arsenical and antihelmintic.

Barber et al. describe their experience in Guatemalas on the 23 volunteers with onchocerciasis by hypodermic injection and the effect. Diagrams were made of skin nodules by swiping followed by examination in saline for microfilaria. Observations were made for the presence of adult worms and were continued for 6 to seven months after the treatment ended. The distribution of skin nodules was followed after administration of antihelmintic containing the alcohols. Outlets of the nodules. Microfilariae were not killed by the drugs and the damage to adult worms was probably slight.

The toxic effect of *As* given parenterally have long been recognized and their nature, frequency and frequency in 74 patients after intramuscular treatment with seven different antihelmintic are described in *How*. In each case the

reactions of varying severity were encountered. It was noted particularly in the case of neostibosan and to a lesser degree with neostam that a tolerance developed to the drug. In contrast to these results with pentavalent compounds, the opposite effect was produced by the trivalent substances Fouadin, anthiomalme and tartar emetic. In some cases urea stibamine produced severe reactions but stibanose was given without untoward effects. The author believes that melarsen oxide is a dangerous drug even in moderate doses.

Cyanine dyes have been found to show remarkable activity in filarial infections and their chemistry is briefly discussed by BROOKER. The chemotherapeutic activity of these substances and related compounds is then discussed by WRIGHT *et al*. The special cages and holders used to facilitate treatment of the cotton rats host are described. [In the reviewer's laboratory cotton rats, used for experimental studies on kala azar, are handled with great ease by a skilled technician without any special apparatus.] Animals were treated every eight hours and received 18 doses of drug. Variations in activity of these substances with alteration in constitution are outlined. The essential structure for activity of cyanines appeared to be a resonating system consisting of tertiary and quaternary nitrogen atoms separated by a carbon chain with an uneven number of carbon atoms and conjugated double bonds.

In a most interesting paper BUEIDING describes the effect of cyanine dyes on the metabolism of *L. carinii*. Both *in vitro* and *in vivo* these substances, in extremely low concentration, inhibit the oxidative metabolism of the parasite. Their curative effect appears to be exerted by this means. The action of cyanines is, moreover, highly specific since concentrations 500 to 1,000 times greater have no effect on the respiration of animal tissues or the activity of various cytochromes. The metabolism of *L. carinii* shows many differences from that of other parasites and would appear to be worthy of closer study.

In a short paper the antifilarial action, toxicology and clinical trials of certain cyanine dyes in human infections are described by PETERS. The cyanines had been selected after tests against *L. carinii* infections of cotton rats along with *in vitro* studies of the metabolism of the adult worm. Although active against cotton rat infections the results in man were disappointing.

KUSHNER *et al* discuss the chemistry of piperazine compounds in the chemotherapy of filariasis. They were interested in obtaining a non-metallic filaricide which could be given orally. As a result of screening experiments in cotton rats the activity of piperazines was discovered. The production of hetrazan (1-diethylcarbamyl-4-methylpiperazine) is a sufficient tribute to the value of these researches. HEWITT *et al* present data on the filaricidal properties of 126 of these compounds including Hetrazan, of which about 20 per cent were active against microfilariae in cotton rats infected with *L. carinii*. They caused an immediate reduction in the numbers of circulating microfilariae, and the adult worms were affected to some extent in the cotton rat and dog hosts. In contrast Sb compounds and cyanine dyes affect adult worms without reducing the microfilarial count. Oral dosage was as effective as parenteral. Later compounds of this type were found to be effective against *W. bancrofti*. Frequent dosage was necessary and toxicity was negligible. The low toxicity of hetrazan was confirmed by HARNED and co-workers who also found that few side reactions resulted from its use. The dosages tolerated by various laboratory animals are recorded. Excretion was found to be rapid by the kidney but the form in which the drug was eliminated has not been determined.

In the final paper of this symposium SANTIAGO-STEVENSON *et al* describe the results obtained by treating 26 Porto Rican patients harbouring the microfilariae of *W. bancrofti* with Hetrazan. All were in-patients and the drug was administered orally at intervals of eight hours in doses of 0.5 to 2 mgm per kilo of body weight over a period of three to 21 days. Although a few

untoward symptoms occurred they were not of a sufficiently serious character to cause discontinuation of treatment. There was a rapid reduction in the microfilarial count. At the end of 160 days after treatment 100 of 24 cases were still negative and in a large percentage of the remainder numbers of microfilariae were reduced. For best result a dose of "mga. per kilo three times daily for two to three weeks" suggested. There was some evidence that adult worms had also been affected.

J. D. Feltus

OTTO, G. F. & MARSH, T. H. Studies on the Chemotherapy of Filariasis. Part I. IV. *Am. J. Hyg.* 1940 July v 50 No. 1 62-141 3F-m. 49ref.

Part I of this series gives a general introduction to the search for effective filarialicidal drugs.

Part II describes the testing of compound 1 *in vitro* on the microfilariae of *Dirofilaria immitis* from the dog. One part of infected blood was mixed with four parts of 0.5 per cent. sodium citrate and five parts of Locke Ringer's solution containing the drug in appropriate concentrations. The final fluid contained over 1,000 microfilariae per ml. and it was incubated at 37°C. The survival of the microfilariae was studied by removing small samples and examining under the microscope. Studies were also carried out on the adult worms of *Litomusculis carinii* obtained from cotton rats and incubated at 30°C. in 4 mm. solution plus 5 per cent. horse serum.

A list is given of 5 non-metallic organic compounds tested on microfilariae. Most of these were inactive but some activity was observed in diethylquaroline

9-chloro-9-(p-dimethylaminophenyl) 10-methylacetaline

4-(p-dimethylaminophenyl) antipyrine and

4-4-dia antipyrine

and another acridine derivative in concentrations of 1 in 10 (10).

Forty-seven metal-organic compounds were tested. Many of the phenyl arsenoxide derivations were highly active (killed microfilariae in concentrations of 1 part of A in a million in 22 hours). Activity was also observed in other tetravalent arsenicals and antimonials but not in mercuric chloride or in pentavalent arsenical or antimonials. The microfilariae of *L. im* were less sensitive *in vitro* than those of *D. immitis*. The adult worms of *Litomusculis* were also more resistant to the chemicals than the microfilariae of *D. immitis* but the results were roughly parallel. Some of the more active phenyl arsenoxide derivations killed the adult worms in concentrations of one part A in a million in 22 hours. The activity of the arsono phenyl arsenoxide derivatives upon microfilariae *in vivo* was compared with their activity for mice. The most variable ratio was given by p-arsono-benzamide. This compound is relatively insoluble but a soluble derivative, the diethylcollate was prepared which was equally active and no more toxic. This compound has been developed further under the name of arsenamide.

The activity of this substance was not impaired by the presence of the water.

Part 3 describes *in vivo* studies on the filariae of dogs and cats with spontaneous infections were used. Drugs or injected into peritoneum daily for five days of the week for 45 days. The animals were killed and the adult worms were examined (usually 10-15 animals per lot). 22 contained total of over 1,200 worms. In one animal 12 per cent. returned 194 in the worms plus 49 dead worms. In one animal 10 per cent. had the worms were dead. The microfilarial count were or an increase during the treatment period but they tended to decrease.

Among the compounds tested there were four trivalent antimonial compounds, these were without any conspicuous antifilarial activity against the adult worms even in high doses (0.3 mgm Sb per kgm per day). Among the trivalent arsenical compounds mapharsen, and the trivalent analogue of carbarsone were also relatively inactive (only two rats treated). Six of the other phenyl arsenoxide derivatives killed all the female worms and many of the males, *viz* the para derivatives with

and arsenamide and melarsen oxide

It is concluded that the specific filaricidal activity of the phenyl arsenoxides is particularly associated with para-amide substitution. [All these results were obtained with only 2-3 rats per compound, so they are suggestive rather than conclusive.]

In animals treated with these arsenical compounds for 45 days, the microfilarial count often fell considerably (>50 per cent) but did not become negative. In two rats which were treated with arsenamide and then followed up for 4-6 months, the microfilarial count gradually diminished, becoming negative after about five months. [This suggests that the main filaricidal activity is on the adult worms, and that the microfilariae disappear gradually from other reasons as their source of replacement has been cut off.]

Of five pentavalent arsenicals examined, two, *viz* p-carbamyl phenyl arsenic acid and melarsen, were active, and so were two pentavalent antimonial compounds, *viz* stibanose and neostibosan. But in view of the promising results already obtained with arsenamide, these were not investigated further. Antimony compounds seem to kill the female worms more readily than male ones. If this were the same in man with *W. bancrofti*, a patient might appear to be cured because the microfilariae disappeared from the blood, but live male worms might persist and continue to stimulate pathological processes.

Part 4 describes therapeutic trials upon *Dirofilaria immitis* in dogs. Arsenicals were given intravenously and antimonials intravenously and intramuscularly. P-arseno-benzamide was given to three dogs in daily doses of 0.45 mgm. As per kgm for 37-43 days. In two, all the adult worms were killed and in the third (which survived for a year) only one female worm escaped. With arsenamide, doses as low as 0.23 mgm As per kgm per day for 11-15 days killed all the adult females, but even much higher doses had no immediate effect on the microfilarial count. [For further details, see OTTO and MAREN, this *Bulletin*, 1947, v. 44, 1083.]

Among the trivalent antimonial compounds tested, sodium antimony thio glycollate killed all the microfilariae but not the adult worms, antimony thio glycollamide gave a similar result (one dog) and stibanose (12 mgm Sb per kgm per day) was ineffective. There was no evidence that the antimonials had produced sterility in the female worms, except in dogs treated with antimony thio glycollamide. In the dogs in which the microfilariae were killed by antimonials, intense leucocytosis occurred.

[These papers describe a large scale careful investigation extending over several years and they should be consulted in the original by those interested in this subject.]

SHOOKHOFF, H. B. & DWORK, K. G. Treatment of *Loa loa* Infections with Hetrazan. *Amcr J Trop Med* 1949, July, v. 29, No 4, 589-93.

Five cases of loiasis were treated with Hetrazan in doses of 100 mgm (1.3-1.7 mgm per kgm) thrice daily for seven to ten days. None showed

Alf had in the blood before (α after) treatment. They had had Calabar swellings and worms in the eye at some previous period during courses of 1-11 years. In all but one patient there was an exacerbation of symptoms when the treatment was started. In one case there was a severe reaction (pyrexia, tachycardia, precordial oppression, tightness of the chest and severe urticaria and angioedema) all but the last two symptoms subsided by the second day and the patient then saw many areas of redness under the skin which may have been the ten round worms. By the end of the week he was feeling well and later he took a second course of Hetrazan. In another patient (whose main symptoms had been pruritus) the pruritus became very severe for the first 24 hours. Otherwise there were no toxic reactions. All the patients were relieved of their symptoms (especially Calabar swellings) by the first course but in 10 relapsed and required a second course.

It is considered that Hetrazan has great therapeutic value for Calabar (but caution is required at the beginning of therapy to minimize allergic reactions).
J. HAYDOCK

MEYERHOFER H. & SCHMID G. Erfahrungen mit Phenothiazin in der Therapie der Oxyurias. Phenothiazine in the Treatment of Enterobiasis. *Deut. med. Woch.* 1949 Aug 28, v. 74 No. 33 311-312.

In Germany after the war say the authors infestation by *Enterobius vermiciformis* increased enormously. Hexylresorcinol was unobtainable and gentian violet hard to get (it was in the old equivalent of the all-momentary English ephemeris in short supply). They therefore tried hexocresol, a locally made preparation of phenothiazine, a drug originally introduced as a urinary disinfectant and later used by veterinarians for helminth infestation by trichostrongylids, strongylids and ascarids. Impure preparations or large doses caused nausea, abdominal pain and diarrhoea, so the authors use pure preparation and prefer small doses and two or more courses to a single course. Larger dosage. For children of 10 years upwards they give a tablet containing 0.7 gm. three daily for 10 days, i.e. 6 gm. altogether. For younger children half this. They have had no patients under three years of age. The tablets are given before food, with a little water. They are tasteless and are therefore taken readily. Of 330 patients so treated, 30 of them children, 139 (9 per cent) were cured (that is, no worms were seen in a two-months follow-up) by one course and 13 more (6.5 per cent) by a second course. See this Bulletin 1949, 46, 961. For an account of a much larger series treated with comparable total doses and for a discussion of possible toxic effect and the precaution to be taken see HAYDOCK J. *ibid.* this Bulletin 1949, 41, 840.

DEFICIENCY DISEASE

CHAILADE C. & G. Le problème de l'alimentation dans les colonies françaises. Dietary Problems and Nutrition in the French Colonies. *J. A. Med. Assoc.* Paris, 1949 Nov. 1, v. 1 No. 8 51-47.

PIERKOWSKI C. Syndrome de dépigmentation-œdème (le kwashiorkor) à Kasal. Therapeutic Trials. *J. A. Med. Assoc.* Paris, 1949 June 30, v. 2 No. 2 231-46. 15 refs.

The author describes a series of cases of deficiency diseases seen in the Belgian Congo in which the clinical features closely resembled the syndrome now generally known as kwashiorkor.

Eleven patients (seven serious) were treated with a preparation of stomach fundus (Ventriculin, Parke, Davis), receiving 10 gm daily for six consecutive days. No improvement was noted in any case.

Sixteen patients (eight serious) were treated with folic acid. They received twelve to twenty doses of 10 mgm spread over two to four weeks. In most cases no improvement was noted, in some there was definite improvement but the author could not satisfy himself that spontaneous remissions might not be responsible.

These careful trials were carried out in the homes of the patients. No attempt was made to control the diet or to eradicate intercurrent infection. The trials show clearly that neither ventriculin nor folic acid is likely to be of any use in a large-scale field campaign against the kwashiorkor syndrome, but they do not preclude the possibility that they might be useful adjuvants to a full therapeutic regime in hospital.

RINEHART, J F & GREENBERG, L D. Effect of Experimental Thiamine Deficiency on the Heart of the Rhesus Monkey. *Arch Pathology* 1949, July, v 48, No 1, 89-95, 2 figs [16 refs]

Five of seven rhesus monkeys subjected to repeated periods of thiamine deficiency showed dilatation of the right ventricle and auricle at autopsy. Four of them showed microscopical changes in the heart muscle. These changes were of two kinds: focal necroses of varying extent and mainly subendocardial, and small areas of cytoplasmic "hydropic degeneration" and irregular nuclear hypertrophy in the fibres of the conduction system. The latter change is considered specific to thiamine deficiency, since it has not been found in controls or in other animals subjected to equally prolonged periods of inanition resulting from deficiency of other substances.

H E Harding

RINEHART, J F, FRIEDMAN, M & GREENBERG, L D. Effect of Experimental Thiamine Deficiency on the Nervous System of the Rhesus Monkey. *Arch Pathology* 1949, Aug, v 48, No 2, 129-39, 9 figs [25 refs]

During the course of repeated deprivations of thiamine, seven monkeys showed in varying degree profound weakness and ataxia: one or more of them also showed signs of cranial nerve weakness or hyperirritability, but no clinical evidence of peripheral neuritis was observed. Examination of the central nervous system at postmortem showed changes which corresponded in a general way to those of Wernicke's encephalopathy, but differed from the latter in several respects. Bilateral symmetrical areas of degeneration confined to the grey matter were found most commonly in the corpus striatum, and were seen also in the globus pallidus, substantia nigra, mamillary bodies, corpora quadrigemina, cerebellar cortex, and in the nuclei of III, VI, VIII and X cranial nerves. The areas of degeneration resembled ischaemic infarcts, but no physical obstruction to the blood supply could be demonstrated: capillary proliferation was found only on the periphery of the older lesions, and was taken to represent an attempt at repair. No pathological changes were found in the peripheral nerves nor in the spinal cord.

HAEMATOLOGY

SPIES, T D, STONE, R E, GARCIA LOPEZ, G, MILANES, F, LOPEZ TOCA, R & ARAMBURU, T. Vitamin B₁₂ by Mouth in Pernicious and Nutritional Macrocytic Anaemia and Sprue. *Lancet* 1949, Sept 10, 454-6, 1 chart

Three chemical substances are known to promote blood regeneration in pernicious anaemia, these are folic acid (pteroylglutamic acid), thymine

(5-methyluracil) and vitamin B_{12} . While the detailed chemical structure of the first two has been determined, that of the third so far has not. Though the first two compounds do not protect the nervous system in cases of pernicious anaemia vitamin B_{12} does do so. Thymine must be given in such large doses (15 gm. daily) that its therapeutic use is impracticable but folic acid has proved therapeutically effective in nutritional macrocytic anaemia and in sprue. Vitamin B_{12} which has been isolated from liver extract and from streptomycin residues is the most potent anti-anaemia substance so far known. It corrects the anaemias of pernicious anaemia, of nutritional macrocytic anaemia and of sprue.

In the present paper are recorded details of the haemopoietic response of three of the 16 cases of pernicious anaemia, two of the 17 cases of nutritional macrocytic anaemia, three of the 14 cases of sprue and one of the two cases of non tropical sprue treated with vitamin B_{12} . All the patients were adults (the youngest of the nine mentioned being 54 years) free from other infections or severe complications, all before treatment had macrocytic hyperchromic anaemia, with a red cell count under three million per cmm. and a colour index over one. In all there was megaloblastic arrest in the spinal marrow. Every patient was on a diet free from meat or meat products during the period of observation and treatment. In some cases treatment was repeated on one to three occasions with variations in dosage. In the actual cases recorded the dosage of vitamin B_{12} ranged from a single oral dose of from 30 microgram. to 1,500 microgram., daily oral dosage for 10 days with 450 microgram. single intramuscular doses of from 25 to 45 microgram. and daily intramuscular doses of 30 microgram. for three days.

The authors conclude from observation of these series of cases that the minimum, maximum, and optimum doses of vitamin B_{12} vary from one patient to another, there is no generally applicable standard dosage. The compound is more effective when given parenterally than orally. Though some patients with megaloblastic marrow arrest do not respond to liver extract or folic acid or to vitamin B_{12} , most do so slowly when vitamin B_{12} is given orally in doses 30 to 60 times as great as those needed parenterally. Treatment by the parenteral route ensures more certain and rapid improvement. Though no allergy or sensitivity to injections of vitamin B_{12} was observed it is probable this will eventually be encountered and in such cases oral treatment may be necessary.

[This interesting and important paper is already summarized. It does not lend itself to further condensation and should be consulted in the original. See also this Bulletin 1949 v 40 No 3.] J. H. D. 4 Jan.

SINGER H. & ROBIN S. Rapid Test for the Demonstration of Sickle Cells and its Clinical Significance. *J Amer Med Ass* 1949, Apr 17, 139, No 16, 1021 & 2 figs. Refs. in footnotes.

The authors describe a simple and rapid test for demonstrating the sickling phenomenon in patients with sickle cell anaemia or the sickling trait.

Sickling can only occur when haemoglobin is present in the reduced state. In this test advantage is taken of the respiratory activity of the red cells and the rapidity with which sickling occurs, independent of the venous oxygenation of the blood cells present, namely the reticulocytes and white cells. It therefore occurs rapidly in all conditions and as rapidly in the fully patent with the trait as in those with anaemia.

The technique is as follows—

One drop of a turbid tooth culture of *Bacterium coli* is mixed with 1 drop of blood, the preparation sealed with paraffin and placed in the incubator at 37°C. Usually after five minutes a positive reaction shows the presence of

characteristic out cells or fully developed sickle cells. If after fifteen minutes no sickling is demonstrable the result can safely be reported as negative.

Repeated washing of the red cells with saline reduces the rate of the reaction but does not abolish the sickling phenomenon. The rate is restored if serum or bovine albumin is added.

The test should be performed as a routine for all negro patients, in view of the numerous syndromes that sickle-cell disease can simulate. There does not appear, however, to be any objection to using as blood donors persons with the trait, since trait cells appear to survive normally when injected into a normal person. [See also WILLIAMS and MACKAY, this *Bulletin* 1949 v 46 774.]

GRIFITHS, S. B. & LIPSCHITZ, R. Haemophilia in a South African Bantu. Report of a Case. *South African Med J* 1919, Aug 27, v 23 No 35 720-21 1 fig.

This case would thus appear to be the first to be reported in a South African Bantu and the second in an African Negro.

VENOMS AND ANTIVENENES

SHILOV, A. *Latrodectus reuensis* sp. nov. from Palestine. Reprinted from *Iscolory* 1918 Apr, v 29, No 2, 209-15, 12 figs. [18 refs.]

A fully illustrated description of the new spider (*Latrodectus reuensis*) is followed by a table of characters by which it may be distinguished from the two species already known to occur in Palestine (*L. VIII-guttatus* and *L. pallidus*). A brief account is then given of some aspects of the life history of the new species and this includes a list of the prey found in thirty-one webs, most of which were beetles but there were other insects and some scorpions and solfugids. Data obtained from a few experiments on the effect of the bite of *L. reuensis* on voles (*Microtus guthriei*) suggest that the venom of this spider is about as potent as that of *L. VIII-guttatus* which killed voles in seven hours.

DONOSO BARRIOS, R. Consideraciones sobre aracnoidismo cutaneo en Chile (Cutaneous Spider-Bites in Chile). *Arch. Uruguayas de Med., Ciruj. y Hig. Ind.* 1918 Nov-Dec, v 33, Nos 5/6 184-206 3 hrs. [58 refs.] In full summary.

[The title of this article is not altogether well chosen for all spider-bites are cutaneous and all are associated in greater or less degree with systemic and not purely cutaneous symptoms.] The author divides aracnoidismo into two clinical forms, the nervous and neurotoxic due in Chile invariably to *L. reuensis* and the cutaneous which is the subject of this contribution.

Three species of spiders with the latter are found in the country. *L. reuensis*, *L. pallidus* and *L. VIII-guttatus* from the Tropics near the border with Peru to the south and to the north the southern variety is almost on the same latitude as the northern one. *L. reuensis* is found in the former production, while the latter seven to eight forms of the sea. These spiders prey on a wide variety of insects and other animals, hence among all patients not only the cutaneous but also the nervous and neurotoxic forms are found. They are found in the following places: 25 and 11 respectively. They are found in the following places: 25 and 11 respectively. They are found in the following places: 25 and 11 respectively.

hide also in crevices in walls of dwellings and behind pictures, in clothes and even in beds. In fact 18 of the 37 were bitten during sleep and 17 were bitten on the neck or arms.

The symptoms caused by the bite of *Loxosceles* Lutz or *L. m. m.* may be divided into three stages. 1. *Early period* the first 24 hours. A prickling sensation like that of a needle followed by burning pain and local oedema (both these symptoms vary considerably from patient to patient) then a "wilted oedema" and pruritus. These may be accompanied by erythema, rarely general pains (in two patients only) vomiting, shivering, bradycardia, jaundice all uncommon and seen in two or three patients only. 2. *Middle period*. Oedema over an area of 20-25 cm. round the site bitten and in 2-4 days usually—but may be earlier—a local necrosis up to 2-4 cm. in diameter with a corona of vesicles and lasting for 2-3 weeks. There may be constitutional symptoms—fever to 38°C (in one who died it reached 39.5°) with rapid pulse and rarely dyspnoea. The blood shows a fall in erythrocytes to about 3 million and in haemoglobin to 35 per cent. Leucocytosis is marked the average is 14,000-15,000 but in one patient it was 24,000. Eosinophils may comprise 20 per cent (in one 30 per cent). 3. *Clearing period*. The scab separates in three weeks or so leaving an ulcer 10-15 cm. in diameter which takes 1 month to heal. The prognosis is grave especially if signs of jaundice and haemolysis are present. Treatment is purely symptomatic no specific serum being yet available. The post-mortem findings in a fatal case are detailed. Locally on the forearm there was a dark, haemorrhagic necrotic mass involving the skin and subcutaneous tissues. Fatty myocardium and blood stained fluid in the pericardium kidneys congested, swelling of the tubular epithelium which was in parts necrotic granular cast vesicles in the interstitial tissue contained haemolysed blood. Liver dark red with yellow zones and marked granulo-fatty degeneration spleen dark and friable blood-stained urine in the bladder.

Scriales globula causes only mild symptoms, local oedema no necrosis a temperature rise to 38°C accompanied by a morbilliform rash mostly on the face chest and arms lasting for 48 hours. Other mild forms were characterized by a fleeting oedema which disappeared in a few hours or by small vesicles which cleared spontaneously in three to four days.

DERMATOLOGY AND FUNGI DISEASES

WARRIS P. Estudio comparado del mal del pinto o enfermedad de Leon Blanco con la otras treponematosis piang, sífilis. Comparative Study of the Treponematosis, Mal del Pinto, Yaws and Syphilis. *Rev. Argent. de Dermatol. y Sifil.* 1944 Jan-June v. 32, Nos. 1-2, 23-9, 7 figs. 16 p.

An interesting account, but containing little more than the facts of the subject. The author considers the diseases mentioned in the title and also helps to point out that the causative organisms are really very closely related. The clinical symptoms group them into two groups. 1. *Primary* the same but that there is no cross-immunity between them. 2. *Secondary* the lesions and signs are not hereditary and are not transmitted by direct contact. The diseases are not hereditary and are not transmitted by direct contact. The diseases are not hereditary and are not transmitted by direct contact.

to treatment, though some lesions may be more severe with endothelial proliferation and small abscesses, but not ulceration, though the epithelial reaction may lead to keratosis and pitting. In yaws and syphilis, tertiary lesions result from an allergic state in the production of inflammatory nodules giant-cells epithelioid proliferation and caseation.

According to the author, the "ides"—palmar and plantar keratosis juxta-articular swellings—constitute the clinical common denominator of the treponematoses, and pintids correspond to lichen, psoriasis and pityriasis, and flat papillomata seen sometimes in syphilis and yaws. The hypothesis is put forward that syphilis untreated for several generations, by change in the body-organism complex evolves into the more benign form, pinta. Much has been written on the common origin of yaws and syphilis, and the same may hold good of syphilis and pinta. But the absence of cross-immunity confirms the actual independence of the diseases in question. León BLANCO has inoculated advanced syphilitics with *T. carateum*, and patients with pinta may develop a syphilitic chancre. KUCZYNSKY in Huryabamba saw a pinta patient with fresh yaws lesions and those having yaws have been seen who later developed pinta. There remains the possibility that mal del pinto has changed its character since pre-Columbian days when, as seen in tombs of the period, it produced bony lesions like those of syphilis and even yaws.

The author concludes with an observation which may be translated

Disregarding the changes which pinta may have undergone in the course of time and through the influx of new peoples, the accounts of Indian historians folk-lore, popular medicine, ceramic exhibits and pre-Columbian osteitis indicate that the three treponematoses have an American origin." H. Harold Scott

PERCLOW M I & RICH, J S. Histoplasmin Sensitivity among Cattle. *Am J Pub Health* 1949 June v 39, No 6, 719-21, 2 figs.

In making a survey of histoplasmosis among small animals especially rodents the culture method is usually employed but this involves much work and the destruction and examination of a great many animals in proportion to the very few found infected. For large animals as for man it is better to use the test of dermal sensitivity to histoplasmin, at least as a preliminary to culture methods.

a slight fall in the percentage of bovine reactors, but a further slight rise in the curve for human reactions.

An observation for which an explanation was not found was the relatively low incidence of reactors (1.1 per cent.) in 150 cattle in two institutional herds on the outskirts of Topeka compared with a rate of 7.1 per cent. reactors among 202 cattle on 71 outlying farms in the same district.

The authors conclude that both human and bovine infections are derived from a common source and that cattle do not constitute an animal reservoir of importance in human histoplasmosis.

[It should be noticed that the investigation related only to dermal sensitivity to histoplasmin, and the determination of active infection has apparently not yet been attempted.]

J. T. Duncan

SMITH C. E., SATO Margaret T., BEARD R. R., ROSENBERGER, H. G. & WHITING E. G. Histoplasmin Sensitivity and Coccioidial Infection. I. Occurrences of Cross-Reactions. *Amer J Pub Health*. 1949 June v 39 No. 6 722-26, 4 figs. [45 refs.]

The coccioidin skin-sensitivity test when properly performed, is accepted as the basis of diagnosis in primary coccioidomycosis. Nevertheless, cross-reactions may occur with extracts of other fungi, especially haplosporangium. In the course of a survey of reactors to histoplasmin, FURCOLOW and NELSON [personal communication] in the State of Ohio found among child reactors to histoplasmin some who also reacted to coccioidin. There is no known endemic focus of coccioidomycosis in Ohio and infection by *Haplosporangium parvum* may be excluded, which leaves the probability that cross-reactions with coccioidin had occurred in children dominantly sensitive to histoplasmin.

In the routine performance of the coccioidin skin test on soldiers arriving for duty in areas where coccioidomycosis exists mild or "equivocal" reactions were sometimes found in men who, apparently had never been exposed to coccioidial infection. An analysis of these cases showed that the majority came from parts of the east-central area of the United States where reactors to histoplasmin are very numerous. Among 3,378 healthy persons who gave negative or equivocal results to the coccioidin test 28 per cent. reacted dominantly to histoplasmin. Equivocal and occasionally positive reactions to coccioidin in persons who had not been exposed to coccioidial infection were found exclusively in the group of reactors to histoplasmin and the frequency and intensity of the coccioidin reaction was in measure with the sensitivity to histoplasmin.

In dominant histoplasmin reactors coccioidin used at a strength 1:10 may cause a strong non-specific reaction which may be misinterpreted, but mistakes can be avoided by the use of the test allergens in high dilution (1:1000). In dominant coccioidin reactors there was a much higher degree of cross reaction. A group of 31 persons who were negative to both coccioidin and histoplasmin subsequently developed coccioidomycosis and became sensitive to both coccioidin and histoplasmin. Dominant coccioidin reactors were also sensitive to histomycin which is allergenically related to histoplasmin.

The persistence of histoplasmin sensitivity was exemplified in a group of six reactors who had lived outside the area of dominant histoplasmin sensitivity for 10 to 21 years. Finally the geographical distribution of histoplasmin sensitivity as shown by the residential histories of the persons examined, confirmed the earlier observations of LAMBERT BLANCHET *J Hyg* 1946 v 21 673, PATON and ALLEN *Blanchet et Hyg* 1948 v 25 1 and CHRISTIE and PETERSON *J Pathology* 1948 v 51 1 J. NEGRONI P Estudios sobre el *Coccidioides immitis* Rixford y Gilchrist
I Micelio vegetativo y fructificacion [Studies on *Coccidioides immitis*
Rixford and Gilchrist I Vegetative Mycelium and Fructification] *Rev Argentina Dermatofilologia* 1948, Jan-June, v 32, Nos 1/2, 50-57, 7 figs
[12 refs] English summary

This is the first of a series of papers dealing with coccidioidomycosis in South America and in it the author gives a description of the microscopic morphology of *Coccidioides immitis* which does not differ from the numerous descriptions of the fungus from North American sources. Reference is made, however, to some characters of the vegetative mycelium usually not included in other descriptions. These are *mycelium en raquette*, appressoria, nodular organs and rudimentary sclerotia. The chlamydospores, the predominant reproductive form, are developed from a differentiated proconidium which may be carried on a pedicle. The tubular proconidium divides into cubical segments of which the apical one forms the first chlamydospore. Below this, alternate segments become spores in basipetal succession, the intervening, atrophic, sterile segments behaving as disjunctors.

Although the systematic position of *Coccidioides immitis* has not been established definitely, many mycologists place it in the Order of *Chytridiales* of the Class *Phycomycetes*, a rare example of a *Phycomycete* pathogenic for animals. The probable existence of sexual phenomena in the species, as suggested by CIFERRI and REDAELLI (*Boll Sez Ital Internaz Microbiol* 1934, v 6, 141), is accepted by Negroni.

NEGRONI, P Estudios sobre el *Coccidioides immitis* Rixford y Gilchrist
II Estudio micologico de las cepas autoctonas y revision del granuloma coccidioidico en la Argentina [Mycological Study of Indigenous Cultures and Revision of Coccidioidal Granuloma in Argentina] *Rev Argentina Dermatofilologia* 1948, Jan-June, v 32, Nos 1/2, 58-65, 4 figs [21 refs]
English summary

Although *Coccidioides immitis* in North America was studied in culture by OPPULS, as far back as the year 1900, DODGE (*Medical Mycology* C V Mosby Co St Louis, 1935) and, more recently, KESSEL [this *Bulletin*, 1941, v 38, 727] have indicated that the fungus in South America has not received similar attention.

Seven cases of coccidioidal granuloma have been identified in Argentina since 1892, when Posadas discovered the disease, and cultures from three of these cases were available for study. From the microscopic morphology of these cultures, described in Negroni's paper I [above], and the macroscopic characters of the colonies it was evident that the North and South American strains of *Coccidioides immitis* belong to one species.

Amongst the physiological tests applied was the auxanographic method of Beijerinck in which the capacity of an organism to utilize various selected substances as sources of necessary carbon and nitrogen is tested. For the carbon auxanogram Negroni used glucose, laevulose, mannose, galactose, rhymnose, maltose, lactose, saccharose, trehalose, raffinose, inulin, dextrin, arabinose, mannitol, glycerol, sorbitol, acetate of soda, citrate of soda, oxalate of soda and tartrate of soda, and found that the monosaccharides and acetate of soda were the most suitable. For the nitrogen auxanogram he used peptone, asparagin, ammonium sulphate, urea and ammonium chloride and found ammonium chloride to be the simplest source of nitrogen.
J T Duncan

VIÑOL, I. *Estudio sobre el *Coccidioides immitis*. III. Estudio micológico comparativo de las cepas Argentinas y Norteamericanas. (Studies on *Coccidioides immitis*. III. Comparative Mycological Study of Argentine and North American Strains.)* *Rev. I. gerencia Dermatol. y Sif.* 1942, July-Dec. v. 72, No. 74, 719-31, 4 figs. English summary.

Previous papers above dealt with the morphology of the vegetative and reproductive stages of *Coccidioides immitis*. They drew attention to some hitherto unnoticed characters and presented a mycological study of three strains of the species isolated in South America. The present paper describes the comparative study of the three South American (Argentine) strains and eight from North America to determine if any morphological or physiological differences exist between the two groups.

In the physiological study, tests were made of the capacity of the vegetative fungi to utilize certain substances as sources of essential carbon and nitrogen as already described in paper II. The results of these tests, set out in tabular form, show that all of the substances examined could be utilized by at least some of the strains, often very freely, and where differences existed among the strains there were not related particularly to the North and South American groups. The most suitable sources of carbon for all strains were D-glucose, saccharides and sodium acetate. Peptone, asparagine, histidine, urea, ammonium sulphate and potassium nitrate were tested as possible sources of nitrogen and all were found to be usable, ammonium chloride being the simplest. The test did not reveal any difference between the North and South American groups. Other physiological properties such as the production of haemolysin, the power to coagulate and digest milk and to liquefy coagulatum were varied with individual strains but the differences had no geographical relationship. The bacteriologically familiar hydrogen sulphide, indole, casein and nitrate reduction tests gave negative results with all strains, and the optimum temperature for vegetative growth was 30°C. for all except one strain (U.S.A. 641).

The addition of a particular animal or vegetable fat—butter, lard, olive oil or olive oil—the culture medium failed to show any difference between the two groups of cultures in respect of the growth of aerial mycelium, production of spores or the depth of colour on the surface or reverse of the colony, but marked differences were found between individual strains.

Coccioides prepared from individual strains from North and South America and tested on guinea pigs inoculated by infection with individual strains of the two groups showed no difference in the reactions elicited.

Finally, morphological tests confirmed the results of the other tests which indicated that authentic strains of *Coccidioides immitis* from North and South America belong to one species. The only exception was strain U.S.A. No. 641, labelled *Ull. tronycosa*, Chicago, Ill. 1941, which appears to be a form of *Sporium fus* and therefore should not have been included in the comparative study.

VIÑOL, I. P. A. VIÑOL, D. *Estudio sobre el *Coccidioides immitis*. IV. Virulencia de las cepas y su relación con los caracteres micológicos. (Studies on *Coccidioides immitis*. IV. Virulence of the Strains and its relation with the Mycological Characters.)* *Rev. I. gerencia Dermatol. y Sif.* 1942, July-Dec. 72, No. 74, 279-81, 1 fig. English summary (10 lines).

In an earlier report (see I. 1942) it was shown that with single possible exceptions (U.S.A. strain 641) 8 strains of *Coccidioides immitis* from the United States and 3 from Argentina, although presenting minor differences, morphologically belonged to the same species. The present report deals with a study of the virulence of these 11 strains and a possible relation of particular

morphological features. The cultures, grown in a synthetic liquid medium were inoculated by the peritoneal route into 65 guinea-pigs. The 11 strains showed wide differences in pathogenicity and virulence as judged by the extent and duration of the disease and its ultimate result, but no relation was found between the pathological effects on the one hand and the morphological peculiarities of a strain or the amount of the living culture inoculated on the other. One strain (No. 694 referred to above), of uncertain authenticity, was wholly non-virulent.

NEGRONI, P., DAGLIO, C. A. N. & BRIZ DE NEGRONI, C. Estudios sobre el *Coccidioides immitis* Rixford y Gilchrist. V. Primera investigación sobre la existencia de una epidemia de coccidioidomicosis en la Argentina. [Studies on *Coccidioides immitis* Rixford and Gilchrist. V. First Investigation on the Existence of an Epidemic Focus of Coccidioidomycosis in Argentina.] *Rev. Argentina Dermatofisiología* 1948, July-Dec., v. 32, Nos. 3/4, 250-63, 8 figs. [25 refs.] English summary.

The discovery, mainly through the use of the coccidioidin skin-sensitivity test, of widespread, mild or subclinical coccidioid infection in endemic areas in the United States, where hitherto the disease, known only in its grave disseminated form, was considered to be relatively rare, prompted a similar kind of investigation in South America. Although coccidioid granuloma was first identified in Buenos Aires by Posadas in 1891, less than a dozen cases of the disease were reported in South America during the following half-century. The identification of a case of coccidioidomycosis in Rio Colorado, Argentina, in October 1947 provided the opportunity to investigate the possible existence of an endemic focus of the disease in the neighbourhood. For this purpose the coccidioidin skin sensitivity test was carried out on children in the primary schools. In the first school dealt with in Rio Colorado, 15 out of 190 children (7.97 per cent) were found to be coccidioidin-sensitive and one child aged 11 showed an intense reaction. Out of 1,834 primary school children examined in General Conesa, Rio Colorado, Choele Choele, Stefenelli, General Roca and Neuquén, 137 had apparently, suffered from asymptomatic coccidioidomycosis. In all, 2,665 school children of ages ranging from 6 to 15 years were examined by means of the coccidioidin test. Of these the highest proportion of reactors was found in Rio Colorado where 10.26 per cent positive and 5.41 per cent doubtful reactors occurred amongst 562 children. In Stefenelli with Gral Roca the corresponding figures were 1 per cent and 1.66 per cent, respectively, and in other areas the proportion of positives ranged from 4.34 per cent to 7.56 per cent. Children in the Rio Colorado area gave not only the highest incidence of reactors but also the greatest frequency of strong reactions.

Judged by the incidence of reactors, the geographical, geological and climatic factors influencing the distribution of the disease were those associated with the arid, steppe-like regions. It is proposed therefore that irrigation should be a first step in dealing with the problem.

Apparently a study of the desert rodents was not included in the survey. (See also this *Bulletin* 1949 v. 46, 167.)

NEGRONI, P. & BRIZ DE NEGRONI, C. Estudios sobre *Coccidioides immitis* Rixford y Gilchrist. VI. Segunda contribución al estudio de la epidemia coccidioidomycótica Argentina. Second Contribution to the Study of Coccidioidomycotic Endemicology in Argentina. *Rev. Argentina Dermatofisiología* 1948, July-Dec., v. 32, Nos. 3/4, 264-6. English summary (7 lines).

This paper is a sequel to the recent report [above] on the examination of primary school children in Argentina by means of the coccidioidin skin test.

The present report deals with the results of similar tests on adults. Reference is made to an earlier study of 6 cases of coccidioidomycosis (Negros paper II above) in persons who had resided in the west of the Province of Córdoba, in the central Pampas and in the Territory of the Rio Negro in areas corresponding in climatic and geological characters to the endemic areas of coccidioidomycosis in the south-western United States.

The present survey embraced 208 adults—178 males and 130 females—who were inmates of five hospitals. Twenty five of these were coccidioidomycosis-positive and 17 others gave doubtful reactions. Of the two sexes, 11.53 per cent. of the females and 5.71 per cent. of the males were reactors. The distribution by residence of persons giving the most marked reactions (+ +) pointed to possible endemic foci in the north and west of the Province of Buenos Aires and the desert areas of the steppe and hill country.

A case of chromoblastomycosis occurring in an Indian is described. The condition was an extensive one involving the right leg (which was amputated) the amputation stump, right hand, forearm, arm, anterior surface of the right upper chest and the left hip.

WHITAKER, H. W., Jr. North American Blastomycosis. Report of a Case in which a Patient with Meningeal Involvement was Treated with Streptomycin and Procin. *Arch. Pathology* 1919 Sept. 1 & 48 No. 9 1-17 4 figs. (Refs. in footnotes.)

"The literature of systemic blastomycosis with meningeal involvement is reviewed, and an additional case in which the patient was unsuccessfully treated with streptomycin and procin is reported in detail.

TROPICAL OPTHALMOLOGY

A REVIEW OF RECENT ARTICLES. LIII

Trachoma.—Trachoma in Afghanistan is discussed in a brief article by HAUM.¹ The disease is very widespread and was present in 85 per cent. of all cases. It occurs in very severe forms and a very great number of all those afflicted go partly or totally blind largely due to lack of even the most elementary rules of hygiene and adequate treatment.

In Afghanistan the disease is spread from one eye to another by flies and repeated wiping of the secretion with dirty rags or the gowns of the women. The latter are used for every possible purpose including blowing of noses and cleaning the eyes of children.

The author considers that the disease is curable provided regular treatment is started in the initial stage and carried on for many months. Prevention of trachoma will only be possible when hygiene can be brought to the inhabitants not only by a doctor but through schools, teachers, church and district officials.

¹ For the 2nd of this Series see Vol. 44, pp. 657-671.

Review of L. Trachoma in Afghanistan. *South African Med. J.* 1919 May 1 22 No. 14 14-15.

A preliminary report on the use of Solufontamide in trachoma is reported by KADER and RADWAN²

This drug is a 33 per cent solution of Fontamide (p amino-benzene-sulphonyl-thiourea). It is a clear, slightly viscous and practically colourless liquid with a density of 1.16 at 15°C and a pH varying from 6.8 to 7.2. The investigation was carried out in Egypt on 60 patients. Usually six subconjunctival injections of one-half to one cubic centimetre each were given in the upper fornix. Two injections were given each week. Treatment was ambulatory and patients were allowed to go home immediately after the administration of the subconjunctival injection.

Very good results were obtained in cases of follicular trachoma, trachomatous ptosis, trachomatous pannus, corneal ulcers and infiltrations and keratitis.

Solufontamide, in addition to its curative effect, is better than other sulphonamide compounds because the subconjunctival injections are painless. It may produce a slight chemosis and subconjunctival ecchymosis which disappear in a few days. No toxic effects occur from its use.

Kerato-Conjunctivitis—Three cases of kerato-conjunctivitis in Hawaii, due to the juice of the crownflower *Calotropis gigantea* are reported by Wong³. In the cases described the milky juice entered the eye when an overhead flower was plucked. The juice contains a powerful toxin which is capable of causing a severe kerato-conjunctivitis, denudes the epithelium of the cornea and conjunctiva, penetrates the cornea and causes an oedema of the corneal substance which results in large folds in Descemet's membrane. There is also an accompanying miosis and congestion of the iris. The marked reduction in vision in the patient is due to the change in the refractive media by the oedema of the cornea. The visual impairment is temporary and varies in duration from five to seven days. There is no permanent injury to the eyes. Treatment is symptomatic.

Trypanosomiasis—Lesions of the optic nerve in African trypanosomiasis are discussed by Toulant, Larmande and Toulant⁴.

In French tropical Africa, it would appear that affections of the optic nerves are very frequent, but the part that the trypanosome plays in the different lesions is still confused.

Bertrand [this *Bulletin*, 1935, v. 32, 476] in 1935 found 40 lesions of the optic nerve, of which 16 were blind, in 707 inhabitants of Tchoho and 12 cases of optic atrophy in 773 inhabitants of Peida (Togo).

Lefrou and Goarnisson [this *Bulletin*, 1939, v. 36, 738] at Onagadougou (Ivory Coast) have examined the eyes in 1,232 cases of trypanosomiasis and found ocular lesions in 31 per cent of recent cases and 20.1 per cent in old cases. But in 537 cases in which the trypanosome was not found similar ocular lesions were present in 22.3 per cent. The lesions found were optic neuritis or papillitis, papillary oedema and optic atrophy.

The two first are found in the second period of the disease and are due to vascular lesions or the presence of the trypanosome in the sheaths of the optic nerve. In sleeping sickness, vascular lesions are characteristic and the trypanosome has actually been found by pathological examination in the sheath of the optic nerve and also in animal experiments.

These two lesions are not serious and usually clear up rapidly without going on to optic nerve atrophy.

²KADER M. A. & RADWAN, M. H. Preliminary Report on the Use of Solufontamide in Trachoma. *J. Roy. Egyptian Med. Ass.* 1948 Nov. v. 31, No. 11 896-9.

³WONG W. W. Keratoconjunctivitis due to Crownflower. *Hawaii Med. J.* 1949, May-June v. 8 No. 5 (33-4), 1 fig.

⁴TOULANT, P., LARMANDE A. & TOULANT M. Les lésions du nerf optique au cours de la trypanosomiose africaine. *Bull. Acad. Na. Méd.* 1949 v. 133 Nos. 23/24 470-84 [40 refs.]

Atrophy of the optic nerve is very commonly found in the ordinary routine examination of eyes in tropical Africa. According to Bertrand, the percentage is from 1.4 to 7.4.

Leffson and Goarnison found percentage to be 1.6 in cases in which the trypanosome was not found and in cases in which it was found the percentage was 7.5 in first cases and 3.5 in old cases. The atrophy is either post-neuritic or primary and can be either partial or complete. Sometimes the optic atrophy is accompanied by choroido-retinitis. It is however questionable whether the choroido-retinitis is a result of the optic nerve lesion or the actual presence of the trypanosome or to the presence of another infection such as onchocerciasis.

In tropical Africa the causes of optic nerve lesions are numerous and as the part played by the trypanosome is uncertain. LAMBLIN and MEYER in their classical monograph in 1904 do not mention ocular complications in trypanosomiasis. HETWET and MEYER scarcely mention them. RIBIER (this Bulletin 1940 v. 43 531) attributes most of the blindness to onchocerciasis. Goarnison states that ocular manifestations are slight and unimportant. On the contrary other authors consider that ocular manifestations are commoner than one is led to believe. DUMAS-MEYER (this Bulletin 1931 v. 31 576) and HANIC consider that 80 per cent. of old cases of trypanosomiasis has narrow retinal blood vessels. History examination prove that ocular complications are rare although the trypanosome can invade the sheath of the optic nerve and retina. The question also arises whether the lesions are due to the direct action of the trypanosome or of a toxin produced by it or allergic reactions produced by the destruction of the trypanosome by drugs or to arachnoiditis involving the optic chiasma.

Other lesions of the optic nerve in tropical Africa which have confusion with those caused by the trypanosome are due to treatment with the arsenical preparation atoxyl and trypanamide. Injections with these drugs have produced permanent defects of vision or blindness. The doses should be small and the preparations freshly prepared and even then optic nerve lesions occur due to hepatic insufficiency. Onchocerciasis has been attributed as a frequent cause of optic nerve atrophy in cases of trypanosomiasis in the Gold Coast.

Syphilis gives the same ophthalmoscopic picture as trypanosomiasis among different workers and 70 per cent. of cases of trypanosomiasis have shown a positive reaction to syphilis. Ankylostomiasis, although common in tropical Africa, cannot be considered a cause of optic nerve lesions.

Vitamin deficiencies are very common among the peoples of tropical Africa and are responsible for lesions of the optic nerve and if they do not explain all the lesions they at least can favour the appearance of ocular complications in the course of trypanosomiasis as they do in arsenical intoxication.

MALTA.—A case of ocular myiasis in Gibraltar is reported by CAS.

The patient was a healthy Spaniard of 75 years of age. Eleven maggots in all were found in the conjunctival sac some of these had burrowed into the cornea. The larvae were identified as those of *Pha. communis* (species not stated). It is probable that the adult fly entered the eye with food and the eye became somewhat injured. The pain became intense with swelling of the eyelids, they arose in and put spots. The conjunctiva was oedematous and very inflamed. After removal of the maggots under cocaine anaesthesia the inflammation subsided.

The most common fly which causes myiasis, being the Muscidae among which the common house fly is the most usual cause of the trouble. If these

flies do lay their eggs in the conjunctival sac, the majority lay them on the surface of the conjunctiva, but some are more dangerous, as these maggots burrow below the conjunctiva and penetrate the globe

The Oestridae possess ovipositors and can lay their eggs beneath the conjunctiva itself and one of them, *Hypoderma bovis*, can penetrate the globe. Such cases of intra-ocular myiasis are very rare

The Sarcophagidae and Anthomyidae can also infect the conjunctiva of man

Cysticercosis—This article by JUNIOR⁶ represents the experiences of the ophthalmologists and pathologist of the Instituto Penido Burnier with 111 patients bearing 116 ocular cysticerci. The parasites were situated as follows—51 in the vitreous, 10, subhyaloid, 44, subretinal, 2 in the anterior chamber, 7, conjunctival, 1 in the orbit, and 1, subcutaneous in the region of the lacrimal sac. The youngest patient was aged 2½ years, the oldest was 66 years of age. There was a slight predominance in women—64 female and 47 male patients. Ocular cysticercosis is a rare disease (116 in 54,000 patients). The majority of the patients were labourers or farm workers who came from rural areas and whose concepts of hygiene were primitive

Ocular cysticercosis obeys the same laws of general infestation as *Cysticercus cellulosae*, the larva of *Taenia solium*

Heteroinfection is more common than autoinfestation. The parasite is found in all the tissues of the eye except the lens. When intraocular, the first symptom is reduction in vision. During the first months of infestation, if the media are clear, the cysticercus can be positively identified by its bluish-white spherical vesicle with peripheral iridescent reflexes and slight undulatory movements. The scolex when evaginated reveals the sucking cups and when invaginated appears as a denser white spot in the centre of the vesicle. When the media are more turbid, diagnosis is more difficult, as the parasite causes an exudative choroiditis and even panophthalmitis. Detachment of the retina, synechias of the iris, complicated cataract and atrophy of the eyeball may occur. The parasite is more often encountered in the inferior vitreous. In 73.2 per cent of cases the complement fixation reaction in the blood is positive and so is a valuable aid in diagnosis

Treatment consists in early extraction of the organism, living or dead, as it is destructive to the eye

Localization of the parasite with non-perforating diathermic cauterizations nearer and nearer to the vesicle should be done until the exact place has been accurately found by ophthalmoscopic examination. It is then removed by the transcleral route

TROPICAL ULCER

BERRY, W T C *Tropical Ulcer Studies in its Causation* *J Roy San Inst* 1949, Sept, v 69, No 5, 625-32 [10 refs]

Tropical ulcer is defined as a sloughing pyogenic lesion, most common on the leg below the knee and usually associated with fusiform bacilli and spirochaetes. The author remarks that probably more money is spent on its treatment than on that of any other single tropical disease and that even if it is treated with success a scar is left which is always liable to break down and lead to deformities. Healthy subjects appear to be relatively resistant to infection,

⁶JUNIOR L. Ocular Cysticercosis [Translated by Charles A PERERA] *Amer J Ophthalm* 1949, Apr v 32 No 4 523-47, 23 figs

and it has been suggested that a deficient dietary is a predisposing cause. It is there is much difference of opinion as to the factors responsible.

The incidence of ulcers was studied in a fishing village on the shores of Lake Nyasa and in a hill village on the escarpment of the Great Rift Valley flanking

nature of abrasions was more severe in the former, being more apt to cause bruising of underlying tissue. The author carried out investigations in the hill village. Forty children were fed with boked dried meat three weekly and the amount was adjusted so as to supply an average of 1.5 grammes of animal protein per lb. body weight daily. It was estimated that an equal or greater amount of vegetable protein was already given in the daily diet. Two control groups were used and it was found that there was no difference between the three groups in relation to total abrasions, the time they took to heal and the number progressing to ulceration.

A group of children was fed for five months on a supplement of baker's yeast. They were given an average daily intake of 0.495 mgm. thiamin, 1.07 mgm. riboflavin and 16.6 mgm. nicotinic acid. The test was carried out at the height of the ulcer season and no controls were used, but the results did not appear to show any advantage in these supplements.

The exudate from 795 consecutive abrasions was stained by Gram's method. Abrasions were at first infected with cocci only, but a typical infection of *Staphylococcus aureus* was superimposed in 120 instances, thus being usually followed by a deterioration in the local condition. It was commoner in the wet than the dry season, while a higher percentage of abrasions healed spontaneously in the latter season. It was considered that mucous flora, more common in the wet, acted as vectors. In one experiment containers filled with fresh blood, frozen rotten fish and pus from ulcers were placed in the open and the flies (*Musca domestica*) although they might alight on one of the five or three containers almost at once moved on to the pus. As a result of three years work the author was deeply impressed by the importance of non-bacterial factors in the causation of tropical ulcers.

A small area over the external malleolus of volunteers was infiltrated with 2 per cent novocain and the outer skin gently pinched away until the blood vessels showed pink through the corium. Pus from a well-established ulcer was smeared on the area and the site protected by a small cardboard cage fixed by a piece of elastoplast which did not get completely round the leg. The subject carried on his work as usual. Seven cases so treated developed ulcers. One volunteer was successfully inoculated over the external malleolus but inoculation over the condyles of both humeri failed. Another who was successfully infected over both external malleoli was treated for three days with one leg turned on Thomas's splint and the other kept lowered to ground level. It was found that when after this both legs were raised the former healed more rapidly than the latter. Two Africans with severe Louis Vincent's infection of the gums were inoculated on the leg and the result but the results were negative. A final malleolus the more extensive trial and investigation of inoculation of volunteers.

A marked difference appears to exist in the severity of the condition in different parts of the world. In the United States 1938-39 15 cases. The author suggests that subjects with inadequate intake of vitamin B complex are hampered in dealing with anaerobic organisms by failure of reduction-oxidation reactions and that the tissues of the leg are at a disadvantage with

those of the arm owing to delay in the superficial venous and lymphatic return, this being possibly accentuated by a mild anaemia

In the ensuing discussion, AMELI (Iran) drew attention to the fact that tropical ulcer was unknown in most parts of Iran, but was prevalent on the shores of the Persian Gulf where the climatic conditions were quite different from those in the rest of the country and where, moreover, fresh fruit and vegetables were scarce and expensive. He thought that fusiform bacilli and spirochaetes were secondary infections and that some other, probably ultramicroscopic, organism was responsible. PROCTOR (observations in Kenya) considered that there was always a dietetic basis to the causation of tropical ulcer, and asked whether lack of vitamin C might not be a predisposing factor.

In reply, Dr Berry said that while no definite proof had been obtained of a specific dietetic cause, yet faults in the diet were so commonly found in association that there was almost certainly something in this. Panda in India had produced ulcers by inoculation of cultures of fusiform bacilli which suggested that ultramicroscopic organisms were not essential. BAKER in Somaliland had concluded that shortage of vitamin C was not a causative factor.

BOIVIN. Le traitement des ulcères tropicaux par les injections intra-artérielles d'Exadyl et de novocaïne et les infiltrations sympathiques lombaires [Treatment of Tropical Ulcer with Intra-Arterial Injections of Exadyl and Novocaïne and Sympathetic Lumbar Infiltration] *Ann Soc Belge de Méd Trop* 1949, June 30, v 29, No 2, 91-7

Exadyl, an amido phenyl hexane compound, occurs in the form of a white odourless powder, soluble in cold water in a 7 per cent solution, very soluble in warm water and warm alcohol, and is administered in a 0.1 per cent solution. The vehicle is not mentioned—presumably it is distilled water or normal saline.

Injections are given twice daily during treatment in 20 ml amounts followed by an injection of 1 per cent novocaïne (20 ml), which, according to the author, is followed by a local rise of temperature accompanied by vaso-dilatation. In very nervous patients a preliminary subcutaneous anaesthesia is administered. In two very severe cases a paravertebral infiltration was given in addition to the intra-arterial injections.

The pulsations of the femoral artery are palpated below the crural canal. A lumbar-puncture needle is used and the left index and middle fingers are placed at the level of the artery while the right hand pushes the needle obliquely inwards to a depth of about 2 or 3 cm, on withdrawing the stylet blood spurts out. The syringe containing the solution is attached and, to make certain that the artery has not been transfixed, pressure is stopped after 1 or 2 ml have been injected and blood flows back into the solution. After injection the patient remains at rest in the horizontal position for ten minutes with a pad fixed to the site of injection. Paravertebral infiltration with 1 per cent novocaïne is carried out according to the standard technique, a Tuffier's needle being used. Exadyl does not cause any toxic reactions.

Phagedenic tropical ulcer is greatly improved by intra-arterial injections of this drug with novocaïne given by the same route or by paravertebral infiltration as an adjuvant. In addition local treatment and administration of bismuth should not be neglected. As the author remarks, the numbers of treatments recommended for tropical ulcer are legion and he considers that their very diversity is a proof of their lack of specificity.

[No mention is made of the possibility of a weak patch occurring in the artery as a result of frequent punctures.]

MISCELLANEOUS DIAPYCNES

BEET, E. A. Primary Splenic Abscess and Sickle Cell Disease. *East Afr. Med. J.* 1949 July 1, 24 No. 7 182-184 10 ref.

An African male aged 25 was admitted to hospital at Broken Hill in Northern Rhodesia on January 21 1949. A week before admission he developed a headache the next day complained of pain in the left side and on palpating this area he felt a tender mass "like a stone". The mass increased in size breathing became difficult and three days before admission he noticed that his conjunctivae were becoming yellow. In 1941 the patient suffered from a left-sided pneumonia and the author suggests that this may have been a splenic infarct.

On admission there was marked wasting with pronounced jaundice of the conjunctivae and pallor of the mucous membranes. The spleen was very enlarged and tender and immobile on respiration. The liver was not enlarged. The patient was afebrile but looked ill and was in great pain.

Blood count: Red cells 2,800,000 per cmm. leucocytes 18,000 (neutrophils 79 per cent.) haemoglobin 8.1 grammes per 100 ml. (Sahl) colour index 1.01 reticulocytes 2 per cent. The red cell morphology was normal and no nucleated red cells, sickle cells or malaria parasites were found. In a sealed preparation of blood (9) to (10) per cent. of red cells showed sickling within four hours. The direct Van den Bergh and Hahn tests were negative.

On January 29 the splenic swelling was softening below the costal margin and there was a definite tympanic note over this organ while the temperature was rising and the patient's condition deteriorating. Aspiration 1½ inches from the midline just below the costal margin produced foul smelling pus followed by 24 oz. of reddish brown pus. 250,000 units of penicillin was instilled into the abscess cavity. On January 31 although the general condition had improved and the temperature had fallen the spleen was still very tender and a drainage tube was inserted into the abscess. 24 oz. of pus were evacuated and continuous drainage into a bedside bottle was begun. 40 oz. of pus subsequently drained away. On February 4 the condition had again deteriorated and the abscess was again drained, much pus being found. A drainage tube was inserted. This drain was removed on February 16 when the condition had greatly improved, the jaundice become less and the spleen smaller and not tender.

On March 8 the patient was up and convalescent. The spleen was still palpable but not tender and the wound was dry. Red blood cells were 4,250,000 per cmm. leucocytes 6,800 per cmm. sickle cell rate and red cell morphology be-

mixture (9) grains daily was administered from January 23 to March 11.

The amount of pus drained is remarked upon 11½ oz. being removed although the actual amount was probably much more. The jaundice was considered to be due to an acute haemolytic process and while the anaemia was ruled out in the following general absence of nucleated red cells and nucleated red cells in blood smears. There were 4 reticulocytes no sickling present after one hour in the sealed preparation. A primary blood rapid increase in the red cell count after surgical drainage of the abscess and administration of iron and fall in the leucocytosis as the patient's infection was overcome. A mixed, a haemolytic anaemia can follow an infection with anaerobic haemolytic streptococci and *C. coli*.

The author however considers that this was due to an infection of an infarct of the spleen the latter being due to splenic infarction within this organ. Owing

to the sluggish circulation in the splenic pulp conditions are favourable to a degree of anoxia sufficient to cause sickling in susceptible red cells, the sickled cells becoming entangled and causing still greater anoxia, thus predisposing to the formation of an infarct which may become infected and go on to abscess formation

[As this condition has not, apparently, been previously recorded in East Africa the clinical picture is fully described.] C F Shelton

TURIAF, J, BLANCHON, P & CABAIL, J L Syndrome de Löffler (formes aiguës fébriles et formes mineures) Asthme et ascariodose [Löffler's Syndrome (Acute Febrile Forms and Minor Forms) Asthma and Ascariasis] *Bull et Mém Soc Méd Hôpit de Paris* 1948, Nos 36/37, 1204-14

The authors have used five cases as a basis for a discussion on Löffler's syndrome

Case (1) The patient had severe asthma-like attacks associated with fever and eosinophilia X-ray showed lung infiltration which had completely cleared in two months The eosinophilia resolved and there was a lymphocytic reaction There were no ova in the stools and chenopodium produced no worms

Case (2) was a true asthmatic who had an attack of Löffler's syndrome with fever, eosinophilia 63 per cent reduced to 21 per cent within a month and to 2.5 per cent after two more months Lung fields cleared in about a month No *Ascaris* were found at the time, but one was passed 18 months later

Case (3) A woman aged 21 who had a history of asthma since the age of five She had a febrile attack with lung symptoms, but no asthmatic attacks There were two areas of infiltration in the left lung, in the sub-clavicular area and at the base The blood picture was at first normal, but later she developed an eosinophilia (14 per cent) The stools showed both *Ascaris* and *Trichuris* Pulmonary tuberculosis was excluded The lung fields cleared within two months, but about three months later she had another febrile attack, this time without X-ray evidence Later, the asthmatic attacks returned and persisted despite treatment but the lung fields were still clear Both worm infections persisted

Case (4) Developed asthmatic attacks at the age of 23 years Several attacks had occurred during the year, but no typical asthmatic history and no associated allergic diseases, or family history were present. When seen a year later the patient had an attack associated with a temporary infiltration of the lung, and an eosinophilia of 17-20 per cent, ending at 13 per cent with a lymphocytic reaction up to 50 per cent No *Ascaris* were found

Case (5) A youth of 16 developed his first attack when he had been in Paris for one month Loss of weight was present, but neither fever nor night sweats there were asthmatic attacks Two episodes of infiltration occurred but with little eosinophilia and that only at second attack (8 per cent) No *Ascaris* were found

The authors first point out that acute febrile forms are not as rare as they are generally considered to be They may take the form of an acute 'pneumopathy' or of a minimal transient lung infiltration with the characteristic radiological and blood pictures A severe case may simulate pneumonia In the minor forms, the diagnosis depends entirely on the radiological picture of small round, sometimes very homogeneous, lesions, which may be mistaken for small tuberculous foci, but which resolve rapidly and compel a revision of the first impression and the associated sharp but transitory rise in the eosinophile count

In their five cases the left lung was involved in four other writers to make a part of the frequency of right lung involvement. They noted a high leucocytosis (37,400 with 83 per cent granulocytes and 163 per cent eosinophils in one case) and in three of their cases that were followed for a sufficient time there a terminal lymphadenosis.

On the subject of aetiology they point out that in only two of their cases was a *T. axei* demonstrated despite the careful and systematic search. They cannot accept the view that Löfller's syndrome can be explained as due to pulmonary ascariasis for this and for other reasons which they give. They consider that transient eosinophilic pulmonary inflammations of an allergic and not a mechanically irritative nature are caused by a variety of foreign organisms or endoparasites and that in the lungs of climatic subjects these organisms find a particularly favorable milieu.

L. F. Nafiz

PROTOZOOLOGY CENTRAL

FRANKEL, J. H. Pathogenesis, Diagnosis and Treatment of Human Toxoplasmosis. *J Amer Med Ass* 1949 May 28; 142 No 4 741-747 5 figs. (Refs in footnotes.)

Four clinical types of *Toxoplasma* infections in human beings are recognized viz. (a) congenital or neonatal meningo-encephalitis (b) atypical encephalitis (c) post-encephalitic sequelae and (d) pneumonitis associated with fever and a rash.

A historical account of toxoplasmosis in animals and man is given, much condensed but with numerous useful references to original sources.

The pathogenesis of the infection is next considered under the head "acute," "subacute" and "chronic toxoplasmosis."

Acute toxoplasmosis

The acute infection is generalized, involving every organ and most tissues although the lesions are microscopic. *Toxoplasma* bodies are found in peripheral macrophages, fibroblasts, reticular and sinusoidal cells, endothelial cells in the lungs, smooth and cardiac muscle and neurons and macrophages of the central nervous system. The clinical symptoms produced may be interstitial pneumonitis, myocarditis, encephalitis, splenitis, hepatitis and orchitis with a cutaneous rash and icterus may be present. Too few human cases in the acute stage have been examined to evaluate the factors operating in the various organic lesions but are seems to be an important factor in the lesions of and at autopsy seem to be more severe and extensive in children than in adults. It has also to be remembered that the cutaneous lesions are asymptomatic especially in adults and may even be no disease.

Subacute toxoplasmosis

This term designates cases in which the infection regresses in the other tissues but continues active or even progressive in the central nervous system and eyes. Most of these cases will have been antenatal or neonatal infection. *Toxoplasma* bodies are not found in the brain tissue but in the central nervous system macrophages which are present everywhere with the presence of *Toxoplasma* bodies. The source of *Toxoplasma* bodies from the other tissues may be explained by the presence there of an acquired immunity whereas this is absent or ineffective in the central nervous system owing to

poor diffusion of serum antibody into brain substance. Another characteristic lesion in the brain is a periventricular reaction zone surrounding the lateral and third ventricles. This consists of four strata indicating, in succession, cellular infiltration and microglial proliferation, thrombosis of large vessels, cellular necrosis and repair.

The clinical symptoms and signs of subacute toxoplasmosis are hydrocephaly and convulsions, chorio-retinitis, retinitis and iridocyclitis. The outcome in subacute cases is often fatal.

Chronic toxoplasmosis

This term designates cases where there is clinical or laboratory evidence of toxoplasmosis but no obvious widespread activity. *Toxoplasma* bodies have not been isolated from such cases and so the question of their persistence or otherwise cannot be answered. The recurrence of active chorio-retinitis in patients showing the scars of subacute toxoplasmosis would favour the theory of persistence as would the occasional finding of apparent *Toxoplasma* pseudocysts in routine autopsy material. The clinical signs and symptoms of chronic toxoplasmosis depend on the damage produced during the acute and subacute stages. The most frequent findings are chorio-retinitis, electroencephalographic evidence of cerebral damage, cerebral calcifications and other signs such as microcephaly, hydrocephaly, ocular malformations and spastic paraplegia.

Transplacental toxoplasmosis

There is much direct and indirect evidence of the antenatal infection of cases and the question arises as to whether the mother contracted toxoplasmosis during pregnancy or had a previous latent infection, allowing a ruptured pseudocyst to infect the foetus *via* the placenta.

Diagnosis

The isolation of *Toxoplasma* from the patient is the final proof of infection, but this is not always possible and immunological and serological procedures of diagnosis have to be undertaken.

Toxoplasma can be isolated in acute cases from the blood, bone marrow, spleen, cerebrospinal fluid and, possibly, sputum.

In the subacute stage the bodies have been found in ventricular fluid and in the brain at autopsy.

Direct demonstration of the bodies in smears is rarely possible except from sedimented ventricular fluid, and animal inoculations must be resorted to. Groups of various animals should be used, mice, hamsters and guinea-pigs, sub-inoculations being carried out if necessary.

The tests to be carried out when no organism can be isolated vary and are enumerated below without details. For these the original descriptions, to which references are given, should be consulted.

The tests denoted are an antigenic test for the demonstration of *Toxoplasma* antigen in ventricular fluid of infants with hydrocephalus, cutaneous tests with *Toxoplasma* antigen (*toxoplasmin*), an *in vitro* test for hypersensitivity to *Toxoplasma* antigen, a *Toxoplasma*-neutralizing antibody test (Sabin & Ruchman) and a *Toxoplasma* complement-fixation test.

Treatment of Toxoplasmosis

Sulphadiazine and sulphamerazine are found to control the infection in animals and the successful treatment of a child has been reported. None of the modern antibiotics has proved effective. In spite of treatment pseudocysts may persist in the brain and possibly give rise to a relapse.

The account ends with a useful summary, in tabular form, of the findings described.

H E Shortt

CROCA J B & ANGSTADT L. The Inflammatory Reaction to *Toxoplasma* in the Omentum and Peritoneal Fluid of the Mouse. *Amer J Trop Med* 1949 July v 29 No 4 473-81 1 graph & 8 figs on 1 pl. (14 refs)

This is an account of the inflammatory reaction in the peritoneal cavity of mice after intraperitoneal inoculation of *Toxoplasma*.

The inoculum used was an "emu-wash" of infected mouse brain in Tyrode's solution.

Eighteen mice were infected and the findings in the peritoneal fluid and omentum recorded at intervals of 4, 8, 12, 24, 48 and 72 hours. The conclusions summarized below appear to have been based on this single experiment and no controls appear to have been used since examination of the peritoneal fluid and omentum of normal mice could hardly be so considered.

After four hours the inoculum had disappeared although rare free forms of *Toxoplasma* were seen then and at 8 hours. After 12 hours intracellular forms were seen in cells of the omentum while after 48 hours numerous free forms were seen both in omentum and in the peritoneal fluid. After 72 hours there was wide dissemination of parasites both in the omentum and in the peritoneal fluid which had increased in amount to 0.5 ml. H E Shaw

ENTOMOLOGY AND INSECTICIDES GENERAL

HOASTEIN M. Notes sur la biologie d'*Aedes aegypti* en Baso-Côte d'Ivoire. Biology of *Aedes aegypti* on the Ivory Coast. *Bull. Soc Path Ex* 1949 v 4, No 48 169-82.

This is a description of two kinds of breeding places of *Aedes aegypti* in the Ivory Coast—one is common between Abidjan and Grand Bassam and consists of thousands of abandoned coconut shells left on the ground in which the mosquito is able to achieve its life cycle from egg to adult in little more than a week. The water in some shells may contain as many as 400 larvae and pupae all of them *Aedes aegypti*. In this area adult mosquitoes invade the houses between 4 p.m. and 8 a.m.

The second area is in the forest region from Abidjan to Agboville and here the breeding places are formed in the piles of cocoa pods on the estates. The adult mosquitoes' behaviour is similar to that of those on the coast but they do not enter houses to the same extent and as they frequent the dense vegetation near the breeding places.

The paper contains a plea for some action to be taken to control these breeding places. H S Lucas

BICKER J C & TAYLOR Marjorie. Radiophosphorus and Radiostrontium in Mosquitoes. Preliminary Report. *Nature* 1949 Aug 5 164-7.

The authors have used radioactive isotopes of strontium and phosphorus administered to the larvae as means of marking adult mosquitoes and studying range of flight and length of life. The method to be preferred for marking adult mosquitoes with pigment and to use them (both isotopes are broken by larvae from the water in which they are living and can be traced later in the body and especially the legs) of the adult mosquitoes. At the concentration which suffices for marking, the animals are not toxic.

After technical development in the laboratory the method was applied to many thousands of adult *Aedes aegypti* which were released near Lagos it appears. Only a minute proportion were recovered (0.1 per cent) in the

largest experiment), [this is characteristic of all work done so far on marking mosquitoes, and makes one accept the results with slight hesitation] The maximum age among females at time of recovery was 28 days, among males a few days only. The maximum distance from point of release was 3,800 feet. The "mosquitoes were distributed largely by wind drift rather than their own flight, although the latter contributed" P A Buxton

FORBES, J & HORSEFALL, W R *Biology of a Pest Mosquito common in New Guinea* *Ann Entom Soc Amer* 1947, v 39, No 4, 602-6 [Summary taken from *Rev Applied Entom* Ser B 1949, July, v 37, Pt 7, 129-30]

Aedes scutellaris scutellaris, Wilk, is one of the most annoying pest mosquitoes in New Guinea and adjacent islands, where it is widely distributed. It is a sylvan species that is adaptable to domestic conditions. Small amounts of water in plant parts and in artificial containers are usual breeding places, and larvae were produced in large numbers in exposed supply and salvage dumps about army camps and once in bilge water in amphibious aircraft. Cartons contained a greater average number of larvae than metal containers, which varied in suitability. Those with lacquer linings were preferred to those without. Metal containers that had been blackened by burning were decidedly less attractive than others. Eggs were sometimes laid in a meniscus about emergent or floating objects or on moist surfaces above water level. Adults tended to remain near breeding-places. Marked females were collected 500 yards from the point of release, but it was observed in two different areas that females did not travel 800 yards in sufficient numbers to cause annoyance. Moderate breezes did not prevent feeding, but strong ones kept the mosquitoes from coming out.

The egg, larval and pupal stages occupied averages of 5, 5.2 and 2 days, respectively. The egg stage varied from 2 to 21 days when the eggs were kept in water continuously. One batch hatched in the laboratory after being kept for 61 days in a moist chamber before submersion. For eggs to remain viable for so long they must first have incubated on a wet surface long enough for the embryo to develop to the hatching stage. Some adults lived six weeks in the laboratory. The mean length of life of 33 females that had an opportunity to feed daily was 21.9 days. Pairing usually took place on the first or second day after emergence. The preoviposition period was about seven days but extended to 25 days in one case. Several batches of eggs may be laid by one female, and the mean number of eggs for caged females was 86.

SMITH, C N & BURNETT, D, Jr *Effectiveness of Repellents applied to Clothing for Protection against Salt-Marsh Mosquitoes* *J Econom Entom* 1949, June, v 42, No 3, 439-44

An account is given of tests made with approximately 3,400 compounds to assess their value as mosquito repellents when applied to clothing rather than to the skin.

Preliminary laboratory tests with *Aedes aegypti* showed that 900 of these compounds complied with the minimum requirements in screening tests, namely fewer than five bites in one minute's exposure daily for ten days. Of these, 375 were available in sufficient quantity for testing in the field where *Aedes taeniorhynchus* and sometimes *Aedes sollicitans* were numerous. The repellents were applied in acetone solution at the rate of 3 gm per square foot to stockings worn successively by three men for five minutes each.

The names are given of 230 of these compounds which were either ineffective or effective for named periods of less than 21 days, 92 substances were effective

for 21 days or longer and the results obtained with these are tabulated. In this table 18 compounds are indicated as being apparently safe for use on children and as being still effective after 24 hours of wear, but a warning is given that most of the substances require additional toxicological investigation before unrestricted use can be recommended. However three of them were of special interest because they are also effective when applied to the skin: these were methyl ester of monethyl oxide oxalic acid (Dulakone), propyl ester of N,N -diethylsorbicinnamic acid and ethyl ester of beta-phenyl- β -hydroxy propionic acid.
H. S. Lacey

FELLOWS, A. & DICKSON, P. Toxicité du S.N.P. sur les puces.
[Toxicity of S.N.P. for *legas ferrous*.] Bull Soc Path Exot. 1949, 42, Nos 5/6, 187-90.

S.N.P. is an abbreviation for N,N -diethyl- α -para-nitrophenyl. Some impurities with small numbers of ticks are reported. Used as a dust at 0.25 to 0.1 per cent and applied at 0.15 mgm. per sq. cm. S.N.P. killed all ticks in 48 hours.

An emulsion of S.N.P. sprayed on to ticks at 1 mgm. liquid per sq. cm. caused intoxication at all concentrations from 0.1 to 0.007 per cent, but the proportions which died over a period of four days were no better than in controls.
J. P. H. 1949

REPORTS SURVIVALS AND MISCELLANEOUS MATTERS

COLONIAL OFFICE. Annual Report on the East Africa High Commission for its Inaugural Year 1948. Colonial No. 913, 26 pp. 4s. 1949 London. H.M. Stationery Office (R.).

The East African High Commission was instituted to take the place of the pre-existing East African Governors Conference. It began to function on January 1, 1948. The Commission consists of the Governors of Kenya, Tanganyika and Uganda. It maintains its own Secretariat and it performs certain inter-territorial services. Among these are some which have bearing on medical matters, particularly the Research and Control Service. The Agriculture and Forestry Research Organisation has acquired large sites near Nairobi for laboratories and experiment stations, along with the Veterinary Research Organisation, and the Agricultural Research Institute at Arusha has been formally absorbed into it. The Veterinary Organisation has also undertaken research into the new drug, streptomycin.

The Tsetse Research Institute (Shinyanga), the Trypanosome Research Station (Tinde) and the East African Tsetse Acclimation Department have been merged into one organisation which will co-ordinate research on tsetse flies and trypanosomes and their control, and will apply the knowledge gained to practical problems. Certain work already done, referred to in confirmation that planned settlement is the real method of reclamation, is of interest because of the finding that *G. falki* can travel along water courses much further than had been expected, and that it can exist much further than known from permanent water.

The report is brief but informative. It will be interesting to see how this principle of inter-territorial co-operation expands in the future, and how vigorous an impetus this publication will give to the research which is so important a part of African development.
Charles H. Short

CONGO BELGE Direction Générale des Services Médicaux Rapport annuel 1948 [Annual Report of the Medical Directorate-General] 109 mimeographed pp, 2 folding maps & 3 charts

The title of the Annual Report on the Public Health in the Belgian Congo [this *Bulletin*, 1949, v 46, 415] has been changed in 1948 to that of Annual Report of the Medical Directorate-General but apart from a valuable introductory chapter summarizing events of special importance and an additional chapter giving a statistical statement of the health of the population, the layout follows in general that of previous reports

The Report contains the familiar detailed list of pestilential and infective diseases, descriptions of medical organizations, governmental and other, port, urban, industrial and general sanitation, and statistical appendices

In the introductory chapter, attention is drawn to the considerable extensions to the hospital organization which have been made or are in contemplation to discussions on closer medical cooperation with French Equatorial Africa, to the Inter-African Tsetse Bureau recently established in Léopoldville as a result of the Trypanosomiasis Conference in Brazzaville in 1948, to the campaign with DDT against the vectors of malaria and onchocerciasis to chemoprophylaxis of malaria, to the acquisition of large quantities of sulphones for trials in the treatment of some of the 60,000 leprosy cases in the Congo and to an intensification of the campaign against tuberculosis In connexion with the last-named subject an admirably realistic and cautious assessment of the problem is given BCG vaccination after Mantoux testing has been adopted and the Medical Department "avec plus de circonspection, malgré la vogue actuelle de la méthode," have turned towards mass radiography, bearing in mind its limited application to the primitive local conditions as compared with conditions in Europe and America It is maintained that this service should be ancillary to existing measures and should develop gradually with them pilot services, of the order of one per Province, will be contemplated in the first instance with the aim of gradual expansion One such post is already in operation and others are being established It is pointed out that the most difficult part of the problem is the treatment of actual cases of tuberculosis "Pneumology Services" are being developed in the principal hospital centres and will be developed as rapidly as possible

The details of diseases show in the main, no gross differences from those reported in 1947 The number of cases and deaths from plague were about halved two cases of yellow fever in Africans were reported from the Eastern Province There were 159 African and 98 European cases of epidemic typhus with three deaths among the former There were 30 European and 12 African cases of *fièvre rouge congolaise* There were 7 cases of sleeping sickness in Europeans with no deaths

A valuable feature of this section is the account of schistosomiasis to which more than two pages are devoted In Europeans there were 162 cases of rectal and 2 of vesical schistosomiasis recorded from the "postes fixes" in Africans, the corresponding figures were 8,374 and 787, with four deaths from each type It is stated that intestinal schistosomiasis is truly autochthonous, but that the vesical type is imported The disease is limited to certain provinces and the various foci therein are listed in considerable detail Reference is also made to additional local surveys, in particular in the fisheries around Lake Albert where 38 per cent of cases of intestinal schistosomiasis were found among some 15,000 people large-scale treatment with tartar emetic and anthiomaline was without incident small-scale trials of Miracid and Hexamidine are also

Book Reviews

46, No 12]

mentioned Chagas's disease naturally has a chapter to itself. Records are given from different States and measurements of endemicity by estimation of the parasitic index, diagnosis by direct blood-examination, by xeno-diagnosis and by animal inoculation, by fixation of complement and the precipitin reaction. Electrocardiography and viscerotomy are considered, and prophylaxis, general and individual. Other diseases discussed are amoebiasis, yaws, pinta, ankylostomiasis, schistosomiasis, filariasis, yellow fever, Rocky Mountain fever, for which a good scheme of inquiry has been organized in São Paulo for diagnosis by observation of suspected cases, collection of ticks in the dwellings and on animals, post mortem material from the heart and the results of liver and spleen puncture, preventive measures are detailed. Trachoma returns for 6 regions in São Paulo in 1938 are given, showing how much greater is the prevalence in rural than in urban schools. Thus, in Aracatuba 54 and 460, in Catanduba 107 and 710 respectively. The chief foci in Brazil are in Ceará, São Paulo and Rio Grande do Sul. *Pemphigus foliaceus*, *fogo selvagem* or "wild re" [see this *Bulletin*, 1946, v 43, 585, 1948, v 45, 464] whose aetiology is still unknown, and various mycoses end this section of the book.

Part III comprises three chapters. In the first the problem of Organization is stated and in the second the difficulties, the chief being the scattered character of the rural population, economic factors particularly the low state of living and general ignorance, deficient data on the epidemiology of rural diseases, the scarcity of men with special knowledge of rural districts—malariaologists, epidemiologists, dentists, sanitary engineers, nurses, etc. In the final chapter proposals for organization of a rural hygiene service are put forward, to include propaganda, education of adults as well as children in health principles, provision of more doctors, health clinics and mutual help in outbreaks, maternity and child-welfare departments, health centres to change the habits and customs if they are insanitary, and to inculcate sounder measures and cure disease.

It will be seen from the foregoing account that much of the information in this book is of local interest, at the same time much that is useful and could be applied in other rural areas can be gathered by careful reading of the work which must be looked upon as a book *suu generis*, almost a pioneer work the composition of which must as we said at the outset, have entailed much labour.

H Harold Scott

LEVI CASTILLO Roberto Atlas de los anofelinos Sudamericanos [Atlas of South American Anophelines] 206 pp, 1 map & 354 figs on 52 pls 1949 Guayaquil Ecuador Tip de la Sociedad Filantrópica del Guayas

Professor Buxton, reviewing a paper by SENFVET [this *Bulletin*, 1948, v 45 1051], has drawn attention to the unsatisfactory state of Anopheline taxonomy in South America. This book does little to improve matters. Many will no doubt wish to use it to supplement the useful keys to larvae and female adults compiled by RUSSELL ROZEBOOM and STONE [this *Bulletin*, 1944, v 41, 325] but they should do so with caution. The author has added keys to eggs and male terminalia and has included certain additional species, most of them described since the publication of the earlier keys. These are —

Culiseta rozeboomi Causey Deane & Deane 1945 and *Anopheles chiriquiensis* Knapp 1946, *Toxorhynchites* Del Ponte & Heredia, 1945 *durlani* Causey, 1945 *heredii* Galvão & Damasceno, 1944, *galao* Causey, Deane & Deane 1943 *laevis* Correa & Cerqueira, 1944, *okloratras* Osorno Mesa, 1947, *canonii* Loch & Abonnenc, 1945, and *costalimai* (Fonseca & Ramos)

eggs and young of birds hibernate in holes in trees and in the ground Where numerous can be a pest in orchards Were regarded as a delicacy by the Romans who fattened them in cages 3-7 young at a birth Introduced in recent years to Buckinghamshire, where they are reported to be spreading, known to local residents as 'Spanish Rats' *Glis glis*"

The author does not necessarily confine himself to the bare minimum, the annotations contain many interesting observations In a few words is told the tragedy of the Norway Lemmings which swarm in certain years, overrun the lowlands and perish in vast numbers in the fjords and sea beyond Then no one can fail to be interested in the story of the domestication of the horse from three centres, one Indo German or Aryan dating from 3000 B.C. originating perhaps in Southern Russia, the second derived from the Western European wild horse giving rise to draught horses and the third the Mongolian stock That does not conclude the information about the horse because different breeds such as Arabs, Barb, etc., are treated separately in annotations of their own The animal kingdom possesses so many curious features, that there is a surprise on almost every page of this book who knows that the sloth derives its protective coloration from the blue and green algae lining the grooves in the hairs, or that the danger signal to a herd of springbok is given by the buck making 10 vertical leaps into the air, with eversion of its dorsal gland?

There are many examples of animals nearly becoming extinct and which have yet just managed to survive by man's intervention One of the most interesting is the case of Père David's deer, a peculiar antelope now unknown in the wild state but originally preserved in the summer palace at Peking The herd was exterminated during the Boxer rising, but by a lucky chance just before this episode some specimens had been sent to Europe and their descendants still survive in the park of Woburn Abbey

The encyclopaedia is illustrated by not very well produced monochrome pictures These could be multiplied with advantage and it would be more useful to have drawings of the rarer animals rather than the tiger or the porcupine

This encyclopaedia might well be called the Baedeker of the Zoo where it would be an ideal companion Apart from the general features the text seems to devote an abnormal amount of attention to the fur trade, there is hardly a page which does not include information about the number of pelts produced annually or the trade names etc This seems a little irrelevant, and a medical reader would welcome the substitution of information regarding zoonosis or the animal reservoirs of disease In only about one instance is this mentioned at present in the case of plague and rats The work would have a greater value to medical readers if the disease-reservoir potentialities had been noted for each animal but perhaps this is too much to hope for In the meantime it can be kept on the shelf of the medical worker ready to consult either for verifying a Latin name or for learning a little about the habits of some animal carrier of disease

P. C. C. Garrlam

the book is 40 pages including 18 pages of text and a table of contents. The historical chapter consists of a number of interesting pieces of information not likely to be met with in the standard text on typhoid fever.

The authors mention that the tick borne typhus of England called by the French *la fièvre des moutons* cannot be distinguished exactly from typhus by louse-bites, and mention a method which they recommended for the early diagnosis of the typhoid fevers.

Although there is a brief description of murine typhus the only reference to the tick borne diseases is the one mentioned above. J. H. B. D. MEYER.

Dr. H. Albert, M.D., Director of the Institute of Tropical Medicine, Liverpool, has revised, with Dr. Louis M.D., D.Sc., etc., *Diseases of the Warm Climates, Their Clinical Features, Diagnosis and Treatment*, pp. xv + 415, 21 charts & 100 figs., 1948. London: William Heinemann—Medical Books Ltd., 99 Great Russell Street, W.C.1. 4s.

This is the promised limited version referred to in the review of the book originally published in French this *Bulletin*, 1949 v. 48, 241.

It is excellently printed and illustrated on art paper and fulfils the English reader all the promises of the original production in French.

The English edition contains a foreword by Dr. Walter A. Sawyer.
